The Mathematization of Economic Theory[†]

By GERARD DEBREU*

I

As the Second World War was drawing near its resolution, economic theory entered a phase of intensive mathematization that profoundly transformed our profession. In several of its main features that phase had no precedent, and it will have no successor. Assessing it requires a multidimensional analysis acknowledging the contributions to economics that were made, as well as the tensions among economists that were heightened.

The development of mathematical economics during the past half-century can be read in the total number of pages published each year by the leading periodicals in the field, an index that I will follow at first. From 1933, the date when they both started publication, to 1959, those periodicals were *Econometrica* and the *Review of Economic Studies*, and the index tells of the decline from a high point, above 700 pages in 1935 to the lowest point, below 400 pages in 1943–1944. But 1944 marked the beginning of a period of explosive growth in which *Econometrica* and the *Review of Economic Studies* were joined in 1960 by the *International Economic Review*, in 1969 by the *Journal of Economic Theory*, and in 1974 by the *Journal of Mathematical Economics*. In 1977, these five periodicals together published over 5,000 pages. During the period 1944–1977, the index more than doubled every nine years. By that measure, 1944 was a sharp turning point in the history of mathematical economics. It was also the year in which John von Neumann and Oskar

Morgenstern published the *Theory of Games and Economic Behavior*.

While the professional journals in the field of mathematical economics grew at an unsustainably rapid rate, the *American Economic Review* underwent a radical change in identity. In 1940, less than 3 percent of the refereed pages of its 30th volume ventured to include rudimentary mathematical expressions. Fifty years later, nearly 40 percent of the refereed pages of the 80th volume display mathematics of a more elaborate type.

At the same time, the mathematization of economists proceeded at an even faster pace in the 13 American departments of economics labeled by a recent assessment of research-doctorate programs in the United States (Lyle V. Jones et al., 1982) as “distinguished” or “strong” according to the scholarly quality of their faculties. Every year the Fellows of the Econometric Society (ES) certify new members by election into their international guild, which increased in size from 46 in 1940 to 422 in 1990. For those 13 departments together, the proportion of ES Fellows among professors was less than 1 percent in 1940; it is now close to 50 percent. It equals or exceeds 50 percent for six of them, which were among those assessed as the eight strongest. So mathematized a faculty expects its students to have what it considers to be minimal mathematical proficiency, and knowledge of calculus and linear algebra is required, or forcefully recommended, for admission to all 13 graduate programs.

Several scholarly recognitions lay additional emphasis on the role that mathematical culture is now playing in our profession. Of the 152 members of the economics section of the American Academy of Arts and Sciences, 87 are Fellows of the Econometric Society; and of the 40 members of the economics section of the National Academy of

[†]Presidential address delivered at the one-hundred third meeting of the American Economic Association, December 29, 1990, Washington, DC.

*Department of Economics, University of California at Berkeley, Berkeley, CA 94720.

Sciences of the United States, 34 are ES Fellows. From 1969 to 1990, 30 economics Nobel awards were made, and 25 of the laureates are, or were, ES Fellows. Since it was first presented to Paul Samuelson in 1947, the John Bates Clark medal of the American Economic Association has been given to 21 economists, of whom 20 are ES Fellows; and of the 26 living past presidents of our Association, 13 are ES Fellows.

One may wish that those counts had not been made. One may argue about points of their interpretation. But they belong in our common knowledge, and their thrust is unequivocal. They indicate how extensive the mathematization of economics and how deep the accompanying change of our field were over the past five decades.

The perception of the depth of that change is reinforced by a comparison of the levels of mathematics required in 1940 and in 1990 to follow the development of economic theory in every direction it was taking. Fifty years ago, basic undergraduate preparation in mathematics was almost always sufficient. Today, graduate training in mathematics is necessary. If, instead of being a follower, one wishes to be an active participant in that development along its most technical avenues, a high degree of mathematical professionalism is called for. Several faculty members of the 13 departments of economics mentioned previously were actually identified as mathematicians by their doctorates; four of them served as chairmen of those departments during the past 25 years. If still sharper focus brings out the intellectual leaders of that development, prominent among them is John von Neumann, one of the foremost mathematicians of his generation.

In that development process, mathematical economics was continuously redefined as new territories were included within its outward-moving frontier and as topics that were once at that frontier became standard parts of the graduate, if not of the undergraduate, economic-theory curriculum.

II

Before the contemporary period of the past five decades, theoretical physics had

been an inaccessible ideal toward which economic theory sometimes strove. During that period, this striving became a powerful stimulus in the mathematization of economic theory.

The great theories of physics cover an immense range of phenomena with a supreme economy of expression. Of this, James Clerk Maxwell (1865) had given a notable example, as he described the electromagnetic field by means of eight equations at the time when mathematical economics was born and came of age in the middle of the 19th century. This extreme conciseness is made possible by the privileged relationship that developed over several centuries between physics and mathematics. In turn, the former presented the latter with open problems, or found to questions raised by physical theory ready-made answers discovered by mathematicians in their abstract universe. Sometimes the causal linkage of research done in each one of the two fields could not easily be unraveled; and, on occasion, the same scientist made inextricably intertwined contributions to both disciplines.

The benefits of that special relationship were large for both fields; but physics did not completely surrender to the embrace of mathematics and to its inherent compulsion toward logical rigor. The experimental results and the factual observations that are at the basis of physics, and which provide a constant check on its theoretical constructions, occasionally led its bold reasonings to violate knowingly the canons of mathematical deduction.

In these directions, economic theory could not follow the role model offered by physical theory. Next to the most sumptuous scientific tool of physics, the Superconducting Super Collider whose construction cost is estimated to be on the order of $\$10^{10}$ (David P. Hamilton, 1990; see also *Science*, 5 October 1990), the experiments of economics look excessively frugal. Being denied a sufficiently secure experimental base, economic theory has to adhere to the rules of logical discourse and must renounce the facility of internal inconsistency. A deductive structure that tolerates a contradiction does so under the penalty of being useless,

since any statement can be derived flawlessly and immediately from that contradiction.

In its mathematical form, economic theory is open to an efficient scrutiny for logical errors. The rigor that has been reached as a consequence is in sharp contrast to the standards of reasoning that were accepted in the late 1930's. Few of the articles published then by *Econometrica* or by the *Review of Economic Studies* would pass the acid test of removing all their economic interpretations and letting their mathematical infrastructure stand on its own. The greater logical solidity of more recent analyses has contributed to the rapid contemporary construction of economic theory. It has enabled researchers to build on the work of their predecessors and to accelerate the cumulative process in which they are participating.

But a Grand Unified Theory will remain out of the reach of economics, which will keep appealing to a large collection of individual theories. Each one of them deals with a certain range of phenomena that it attempts to understand and to explain. When it acquires an axiomatic form, its explicit assumptions delimit its domain of applicability and make illegitimate overstepping of its boundary flagrant. Some of those theories take a comprehensive view of an economic system and bring insights into the solutions of several global problems. For instance, prices contribute to achieving an efficient use of resources, to equalizing supply and demand for commodities, and to preventing the formation of destabilizing coalitions. In every case, a theoretical explanation must be provided. The assumptions, which cannot be satisfied by all economic observations, are the present outcome of a continuing weakening process.

A global view of an economy that wants to take into account the large number of its commodities, the equally large number of its prices, the multitude of its agents, and their interactions requires a mathematical model. Economists have successfully constructed such a model because the central concept of the quantity of a commodity has a natural linear structure. The action of an agent can then be described by listing the quantity of its input or output for each

commodity (opposite signs differentiating inputs from outputs). That list can be treated as the list of the coordinates of a point in the linear commodity space. Similarly, the price system of an economy can be treated as a point in the linear price space, dual of the commodity space, whose dimension is also the number of commodities.

In those two linear spaces, the stage was set for sometimes dazzling mathematical developments that began with the elements of differential calculus and linear algebra and that gradually called on an ever broader array of powerful techniques and fundamental results offered by mathematics. Thus, the three roles of prices given earlier as instances were illuminated by basic mathematical theorems: the first, the achievement of an efficient use of resources, by results of convex analysis; the second, the equalization of supply and demand for commodities, by results of fixed point theory; the third, the prevention of the formation of destabilizing coalitions, by results of the theory of integration and of nonstandard analysis. In those three cases, the lag between the date of a mathematical discovery and the date of its application to economic theory decreased over time. It was notably short for nonstandard analysis, founded at the beginning of the 1960's by Abraham Robinson¹ and applied to economics by Donald Brown and Abraham Robinson (1972).

The last, and most recently developed, of those three instances can be chosen, as can either of the other two, for a more detailed illustration. Competition is perfect when every agent's influence on the outcome of economic activity is insignificant. The influence of their totality on that outcome is, however, significant. It is to solve the problem of aggregating negligible quantities so as to obtain a nonnegligible sum that integration was invented. In this perspective, the application of integration theory to the study of economic competition is entirely natural. That application requires the set of agents to be large—larger than the set of integers. Treating the set of the agents of an economy as the rich collection of the points

¹See the preface in Robinson (1966).

of an interval of real numbers has long been familiar in descriptions of economic data. It became familiar in economic theory as well after Robert J. Aumann (1964) showed that, in a pure exchange economy composed of insignificant agents, the formation of destabilizing coalitions is prevented if and only if all those agents base their decisions on a price system.

The concept of a convex set (i.e., a set containing the segment connecting any two of its points) had repeatedly been placed at the center of economic theory before 1964. It appeared in a new light with the introduction of integration theory in the study of economic competition: if one associates with every agent of an economy an arbitrary set in the commodity space and if one averages those individual sets over a collection of insignificant agents, then the resulting set is necessarily convex.² But explanations of the three functions of prices taken as examples can be made to rest on the convexity of sets derived by that averaging process. Convexity in the commodity space obtained by aggregation over a collection of insignificant agents is an insight that economic theory owes in its revealing clarity to integration theory.

An economist who experiences such an insight belongs to the group of applied mathematicians, whose values he espouses. Mathematics provides him with a language and a method that permit an effective study of economic systems of forbidding complexity; but it is a demanding master. It ceaselessly asks for weaker assumptions, for stronger conclusions, for greater generality. In taking a mathematical form, economic theory is driven to submit to those demands. The gains in generality that it has achieved as a result, in little more than a century, stand out when the first formulations of the theories of general equilibrium (Léon Walras, 1874–1877) and of the core of an economy (Francis Y. Edgeworth, 1881 pp. 34–8) are placed side by side with the recent treatments of those subjects to which *The New Palgrave* is an introduction and a

bibliographical key (John Eatwell et al., 1987–1989). Walras's consumers and producers have been freed from many of their constraining characteristics; Edgeworth's universe of two consumers and two commodities has been vastly expanded.

Mathematics also dictates the imperative of simplicity. It relentlessly searches for short transparent proofs and for the theoretical frameworks in which they will be inserted. Participating in that pursuit, economic theory was sometimes drawn by drives toward greater generality and toward greater simplicity in the same direction, rather than in opposite directions. Cohort after cohort, students of consumer theory have learned about the concept of decreasing marginal rate of substitution for two commodities on an indifference curve and about its extension to the multicommodity case. Notably more general, and notably simpler, is the concept of convexity of the set of points preferred to a given point in the commodity space. Welfare economics presents another instance. One of its main theorems formulates precisely the principle enunciated by Adam Smith (1776). If all the agents of an economy are in equilibrium relative to a price system, then they utilize their collective resources optimally. The proof of that theorem (Kenneth J. Arrow, 1951) has become so simple that it can be given without mathematical symbols. It is, at the same time, of utmost generality; in relating two basic concepts of economic theory to each other, it uses no assumption.

In its attempts to attain its many objectives, economic theory was helped by greater abstraction. Preference theory supplies an example again. Significant research efforts were expended on solutions of the integrability problem. That problem can be bypassed altogether, and greater simplicity can be achieved by moving from the commodity space to the more abstract space of the pairs of its points. In this space, whose dimension is twice the number of commodities, the pairs of commodity points indifferent to each other are now assumed to form a smooth (hyper)surface. As another instance of the generality permitted by abstraction, consider the notion of a commod-

²On this direct consequence of a theorem of A. A. Lyapunov, see Karl Vind (1964).

ity, which can be treated as a primitive concept, with an unspecified interpretation, in an axiomatic economic theory. A newly discovered interpretation can then increase considerably the range of applicability of the theory without requiring any change in its structure. Thus, by making the transfer of a good or service between two agents contingent on the state of the world that will obtain, Arrow (1953) made possible the immediate extension of the economic theory of certainty to an economic theory of uncertainty by a simple reinterpretation of the concept of a commodity. The theory of financial markets has been influenced by that view of uncertainty, and their practice has not been unaffected. Finally, take the problem of existence of a general equilibrium, once considered to be one of the most abstract questions of economic theory. The solutions that were proposed in the early 1950's paved the way for the algorithms for the computation of equilibria of Herbert E. Scarf (1973) and for several of the developments of applied general equilibrium analysis (Scarf and John B. Shoven, 1984). In this case, abstraction in economic theory led to the study of fundamental problems of great generality, but also to a broad range of applications.

III

The list of advances that the mathematization of economic theory helped or permitted is already long; and in one aspect it may appear lengthy. *Ceteris paribus*, one cannot prefer less to more rigor, lesser to greater generality, or complexity to simplicity; but other things are not equal, and in the estimate of many members of our Association the cost of that mathematization sometimes outweighs its benefit. Two of its presidential addresses notably confronted that difficult analysis and stressed the price that economics paid for its increased use of mathematics. Wassily Leontief's (1971) observations were factual, and Robert A. Gordon's (1976) comments relevant when they were made in 1970 and in 1975. They still are today, for, in spite of their authorities, enhanced by the platform from which they

were speaking, and in spite of the wide diffusion of their critiques, neither Leontief nor Gordon altered the course of the development they were assessing. In the past two decades, economic theory has been carried away further by a seemingly irresistible current that can be explained only partly by the intellectual successes of its mathematization.

Essential to an attempt at a fuller explanation are the values imprinted on an economist by his study of mathematics. When a theorist who has been so typed judges his scholarly work, those values do not play a silent role; they may play a decisive role. The very choice of the questions to which he tries to find answers is influenced by his mathematical background. Thus, the danger is ever present that the part of economics will become secondary, if not marginal, in that judgment.

The reward system of our profession reinforces the effects of that autocriticism. Decisions that shape the career of an economic theorist are made by his peers. Whether they are referees of a journal or of a research organization, members of an appointment or of a promotion committee, when they sit as judges in any capacity, their verdicts will not be independent of their own values. An economist who appears in their court rarely ignores his perception of those values. If he believes that they rate mathematical sophistication highly, and if he can prove that he is one of the sophisticates, the applause that he expects to receive will condition his performance.

The same effects are also amplified by the relentless pressure to publish exerted by his environment. There are indeed instances of extreme restraint in scientific publication, and some of them have become legend. The mathematical papers of Bernhard Riemann (1826–1866) take 506 pages in the volume that collected them (Riemann, 1876). The molecular structure of DNA was announced by James Watson and Francis Crick (1953) in a one-page article. But it is easier to explain those examples away than to follow them. The environment of a scholar demands papers, and the temptation to supply them without restraint may become over-

powering to an economic theorist who has developed proficiency in his research style. The precocious development of that proficiency is a comparative advantage that a mathematical approach bestows on him.

The spread of mathematized economic theory was helped even by its esoteric character. Since its messages cannot be deciphered by economists who do not have the proper key, their evaluation is entrusted to those who have access to the code. But acceptance of their technical expertise also implies acceptance of their values. Our profession may take pride in its exceptional intellectual diversity, one of whose clearest symbols is an Ely lecture given by an economic historian at a session chaired by a mathematical economist. Yet that diversity is strained by the increasing impenetrability to the overwhelming majority of our Association of the work done by its most mathematical members.

IV

The bond that ties economists together in their study of a common subject has not been tested only by differences in methodologies. It has also been tried by differences in ideologies. In their endeavors to make their field into a science, economists must renounce a favorite mode of thinking—wishful thinking; they must be impartial spectators of a play in which they are the actors. While they attempt to keep that inhuman stance, they are pressed to give immediate answers to societal questions of immense complexity and thereby to abandon the exacting slowness of the step-by-step scientific approach. Divisions according to methodologies and ideologies, criticism from outside and from inside, and intellectual fashions that sweep our discipline make each one of its steady developments remarkable. The mathematization of economic theory was one of them for a century and a half. During the past five decades it became one of the prime movers in the transformation of our field. The extent of that mathematization has given rise to discordant assessments of its effects and to attempts to change its heading. The quality of assess-

ments of the phase that economic theory underwent and the effectiveness of attempts to alter the course of its evolution will gain from a detailed analysis of the processes that led to its present state.

An Econometric Analysis of U.K. Money Demand in *Monetary Trends in the United States and the United Kingdom*

by Milton Friedman and Anna J. Schwartz

By DAVID F. HENDRY AND NEIL R. ERICSSON *

This paper evaluates an empirical model of U.K. money demand developed by Milton Friedman and Anna J. Schwartz in Monetary Trends in the United States and the United Kingdom. Testing reveals misspecification and hence the potential for an improved model. Using recursive procedures on their annual data, we obtain a better-fitting, constant, dynamic error-correction (cointegration) model. Results on exogeneity and encompassing imply that our money-demand model is interpretable as a model of money but not of prices, since its constancy holds only conditionally on contemporaneous prices. (JEL 210)

In their 1982 book, *Monetary Trends in the United States and the United Kingdom: Their Relation to Income, Prices, and Interest Rates, 1867–1975*, Milton Friedman and Anna Schwartz present a wealth of empiri-

cal findings as support for a range of economics hypotheses.¹ To isolate the longer-term relationships that are their primary concern, Friedman and Schwartz estimate their empirical models from data transformed by averaging annual observations over phases of NBER reference cycles. In our analysis, we first replicate one of their preferred models for U.K. money demand on the phase-average data and then evaluate it econometrically to investigate aspects of model specification about which the data are most informative. The outcome indicates the potential for an improved equation but does not entail the form of respecification required. In seeking to construct an improved model, we formulate an equation that integrates long-run properties with short-run dynamics, based on the recent merging of the theories of error-correction and cointegration. Moreover, because phase-averaging may entail a loss of information about relevant parameters, we return to analyzing the underlying annual observations. Finally, the resulting model is critically evaluated.

*Hendry is Professor of Economics at Nuffield College, Oxford, England OX1 1NF, and Visiting Research Professor at the Institute of Statistics and Decision Sciences, Duke University, Durham, NC 27706; Ericsson is a staff economist in the International Finance Division, Federal Reserve Board, Washington, DC 20551. This research was supported in part by U.K. Economic and Social Research Council (E.S.R.C.) grants HR8789 and B00220012. We are grateful for the financial assistance from the E.S.R.C. although the views expressed in this paper are solely the responsibility of the authors and should not be interpreted as reflecting those of the E.S.R.C., the Board of Governors of the Federal Reserve System, or other members of their staffs. Helpful discussions with and comments from Chris Allsopp, Julia Campos, Nicholas Dimsdale, Rob Engle, John Flemming, Milton Friedman, David Germany, John Geweke, Dale Henderson, Kevin Hoover, Jeroen Kremers, Bonnie Loopesko, Mary Morgan, John Muellbauer, Adrian Neale, Charles Nelson, Jean-François Richard, Ken Rogoff, John Taylor, Ken Wallis, Arnold Zellner, and several anonymous referees are gratefully acknowledged. We are indebted to Jeroen Kremers, Cathy Fitzgerald, and Aileen Liu for their invaluable assistance with the calculations. This is an extensively revised and shortened version of papers presented to the Bank of England's Panel of Academic Consultants (Hendry and Ericsson, 1983) and circulated by the Federal Reserve Board (Hendry and Ericsson, 1985).

¹For helpful reviews and summaries of Friedman and Schwartz (1982), see inter alia Charles Goodhart (1982), Thomas Mayer (1982), Tim Congdon (1983), Basil Moore (1983), and Michael Artis (1984).

The sequence in the previous paragraph involves a natural progression from model discovery to model evaluation through replication and testing, and then via new conjectures back to discovery, seeking models that account for previous findings and explain additional phenomena. The paper's main objective is to achieve this last goal for U.K. money-demand models over the period 1878–1970. An additional objective is to exposit an econometric framework that makes precise the notion of an improved model, explains the construct of accounting for previous findings (denoted encompassing), and delineates the criteria for model evaluation. This enables us to clarify the concepts of exogeneity, invariance, encompassing, and cointegration in the context of an important economics debate. The empirical model reported below improves upon the phase-average U.K. money-demand equation from Friedman and Schwartz, our first annual-data specification (proposed in 1983), and those in the studies that the latter stimulated, thus illustrating a progressive research methodology in action.

In Section I, we consider the data and data transformations used by Friedman and Schwartz (1982). In Section II, we discuss the money-demand relationships they estimated from the phase-average data for the United Kingdom and evaluate many of their empirical claims about the selected money-demand equation. The statistical framework and its associated concepts are briefly explicated in Section III to clarify the joint destructive and constructive roles for tests. In Section IV, we constructively apply that approach to modeling money demand using the annual U.K. data series. Our conclusions are presented in Section V.

I. The Data Series and Transformations

In Friedman and Schwartz's (1982) and our studies of U.K. money demand, the basic data series are annual values for the United Kingdom from 1871 to 1975 of the broad money stock (M), real net national income (I), the price level (P), short-term and long-term nominal interest rates (RS and RL), population (N), and high-powered

FIGURE 1. THE LOG OF THE VELOCITY OF MONEY (v_t) AND THE YIELD ON THREE-MONTH BILLS (RS_t) (ANNUAL DATA)

FIGURE 2. THE LOG OF THE REAL MONEY STOCK $([m - p]_t)$ AND THE LOG OF REAL INCOME (i_t) (ANNUAL DATA)

money (H); and the price level (P^*) in the United States. All series are in Friedman and Schwartz's tables 4.8 and 4.9; for details of construction and definition of the series, see both Friedman and Schwartz (1982 Ch. 4, 5) and our Appendix, which note reservations on the measurement and interpretation of those series. Unless otherwise indicated, capital letters denote both the generic name and the level; logs of scalars are denoted by lowercase letters. Figures 1, 2, and 3 respectively show the annual time series for velocity V ($\equiv PI/M$) and RS, real money (M/P) and real income, and nominal money and prices.²

From Figure 1, three distinct episodes are discernible in the behavior of velocity, coinciding with historical periods before the First World War (1871–1914), interwar (1918–1939), and after the Second World War (1945–1975). Initially, velocity and RS cycle around constant levels. Then, in the inter-

war period, velocity is lower and more volatile. It falls during the Second World War, reaching its lowest observed level in 1947, corresponding to the lowest level for interest rates (of 0.5 percent per annum). Next, velocity trends upwards, more than doubling by 1970, while interest rates fluctuate increasingly around an upward trend. Finally, between 1971 and 1975 velocity falls while RS rises.

Some insights into this behavior of velocity can be gleaned from Figure 2, which plots two of its constituents, $m - p$ and i . The interwar period begins with a sharp fall in i being matched by a large rise in $m - p$, which then remains systematically above i with its greatest departure from i in 1947. Thereafter, $m - p$ falls steadily until around 1960, whereas i rises considerably, and then $m - p$ "levels off" until its sharp rise in 1971. Thus, between 1947 and 1970 measured velocity more than doubles because $m - p$ drops while i rises. Lastly, Figure 3 shows nominal money and the price level. These series are highly correlated in levels although, overall, money increases 5.6 times

²When there is no loss of clarity, we often refer to v ($= p + i - m$) as velocity.

FIGURE 3. THE LOG OF THE NOMINAL MONEY STOCK (m_t) AND THE LOG OF THE IMPLICIT PRICE DEFLATOR (p_t) (ANNUAL DATA)

relative to p (real income increases by 6.7 times), and during 1920–1922 a large fall in p occurs alongside a small fall in m . To represent adequately the century of data, an econometric model of U.K. money demand must encompass such features.

Since Friedman and Schwartz aim to examine the long-period movements in the data, they do not analyze these annual series directly but first transform them by averaging separately over contraction and expansion phases of data-selected choices of reference business cycles. From some hundred years of annual U.K. observations, Friedman and Schwartz identify 37 such phases with average lengths of 2.1 and 3.4 years respectively for contraction and expansion phases. These phase averages, weighted by a function of duration, are the basic units of analysis (pp. 75–9 and table 5.8)³ and are analyzed both in levels and as

rates of change. The latter are calculated from least-squares slopes fitted to triplets of overlapping phases (weighted appropriately) and are arithmetically nearly the same as differences from one expansion (or contraction) to the next.⁴ The data to which these moving-average filters are applied are the logarithms of money, prices, incomes, and population, and the original values of interest rates. We denote phase-average data by an overbar (e.g., \bar{m}_j for the j th of J phase-average observations of the logarithm of money stock). These data are the basis for the analysis in Section II, whereas in Section IV we utilize the original annual time series. The relationship between the phase-average and the annual series for velocity is shown in Figure 6, discussed below.

³Unreferenced page numbers and table numbers when “table” is uncapitalized refer to Friedman and Schwartz (1982).

⁴There are typographical errors in the reported values for “rates of change” in table 5.10 affecting observations 18–21. We corrected those errors following the procedures described by Friedman and Schwartz (1982 section 3.2); our amendments are reported in Hendry and Ericsson (1985 appendix F).

II. Testing the U.K. Money-Demand Model on the Phase-Average Data

In this section, we summarize the central empirical results obtained by Friedman and Schwartz (1982) for U.K. money demand using the phase-average data, replicate one of their preferred models, and econometrically evaluate it. Table 1 reports estimates of four equations out of those that Friedman and Schwartz record for the United Kingdom as establishing evidence concerning the demand for money, and the influences of money on income and on prices. "Levels" and "rates of change" equations are analyzed by Friedman and Schwartz but, as they see little to choose between them (e.g., see p. 286), we focus on the equations in levels: full details can be found in Friedman and Schwartz. We summarize their interpretation of the estimates in Table 1 as follows. Equation (a) is their preferred U.K. money-demand equation and has a nearly

unit income elasticity (pp. 280–4). From equation (d), I does not depend upon M , whereas P does [eq. (c)] and, hence, so does PI [eq. (b)] (cf. pp. 422, 351).

Equations (a)–(d) represent types of models (of money, nominal incomes, prices, and output, respectively), but from our perspective their joint existence raises difficulties. Because M is a regressor in equations (b)–(d), M must be (weakly) exogenous if the coefficients in these regressions are to be interpreted as parameters of interest (cf. Robert Engle, Hendry, and Jean-Francois Richard, 1983). With M exogenous, equation (a) is determining P , not M ; but so is equation (c). Conversely, if M does not maintain its exogeneity status in equation (a), P and M are jointly determined, and hence equation (c) must be invalid. However, since Friedman and Schwartz take (a) as one of their "final equations" for U.K. money demand (p. 281), we will evaluate it on that basis.

TABLE 1—EQUATIONS FOR U.K. MONEY DEMAND, NOMINAL INCOMES, PRICES, AND OUTPUT FROM FRIEDMAN AND SCHWARTZ (1982) (PHASE-AVERAGE DATA)

Equation	Source
(a) $(\bar{m} - \bar{p} - \bar{n}) = 0.16 + 0.88(\bar{i} - \bar{n}) - 11.16\bar{RN} - 0.22G(\bar{p} + \bar{i}) + 1.4\bar{W} + 21\bar{S}$ (0.08)(18.13) (3.42) (0.74) (2.38) (7.56) $(\hat{\sigma} = 5.54, R^2 = 0.970, dw = 1.51, \eta_1[18, 12] = 6.3)$	p. 282
(b) $(\bar{p} + \bar{i}) = 0.38 + 1.01\bar{m} + 14.17\bar{RN} + 0.53G(\bar{p} + \bar{i}) - 1.1\bar{W} - 19\bar{S}$ $(\hat{\sigma} = 5.99, R^2 = 0.9977, dw = 1.33, \eta_1[18, 12] = 5.7)$	p. 349
(c) $\hat{p} = -5.99 - 0.015\bar{i} + 1.02\bar{m} + 0.94\bar{RS} - 1.10G(\bar{p} + \bar{i})$ (31.1) (7.4) (17.4) (0.9) (2.8) $(\hat{\sigma} = 6.0, dw = 1.01, \eta_1[15, 10] = 3.1)$	p. 420
(d) $\hat{i} = 6.50 + 0.017\bar{i} - 0.05\bar{m} + 2.34\bar{RS} + 2.20G(\bar{p} + \bar{i})$ (34.2) (8.3) (0.9) (2.4) (5.7) $(\hat{\sigma} = 5.9, dw = 0.97, \eta_1[15, 10] = 2.1)$	p. 420

Notes: Notation is as in Sections I and II, but here parentheses enclose t values, as reported in the original text. No t ratios or standard errors appear in Friedman and Schwartz (1982) for the equation labeled (b) above. $RN = (RS) \cdot H/M$; $G(\cdot)$ denotes a rate of change; and \bar{W} and \bar{S} are the dummies for postwar adjustment and demand shift, rescaled by 1/100 (see Appendix). Phase averages 12–14 and 24–26 are omitted in (c) and (d). Here and in Table 3, values of $\hat{\sigma}$ with logarithmic regressands are quoted as approximate percentages relative to the level of the regressand in its original units [e.g., if $\log(Y)$ is the regressand, $\hat{\sigma}$ is a percentage of Y]. Values for dw and η_1 are our calculations and are not reported in Friedman and Schwartz. Our equations replicating (c) and (d) had somewhat smaller values of $\hat{\sigma}$ than those in Friedman and Schwartz.

We could closely replicate equation (a):

$$\begin{aligned}
 (1) \quad & \overline{(\bar{m} - \bar{p} - \bar{n})}_j \\
 & = 0.012 + 0.885(\bar{i} - \bar{n})_j \\
 & \quad (0.19) \quad (0.049) \\
 & - 11.21\overline{RN}_j - 0.22G(\bar{p} + \bar{i})_j \\
 & \quad (3.3) \quad (0.29) \\
 & + 1.37\overline{W}_j + 20.6\overline{S}_j \\
 & \quad (0.58) \quad (2.7)
 \end{aligned}$$

($J = 36$, $\hat{\sigma} = 5.66$ percent, $dw = 1.51$, $R^2 = 0.97$) where \overline{RN} is the differential between \overline{RS} and the "own-yield" on money, $G(\bar{p} + \bar{i})$ is the growth rate of nominal income (interpreted by Friedman and Schwartz as proxying for the rate of return on physical assets), \overline{W} is a dummy for "postwar adjustment" (p. 228), and \overline{S} is a data-based dummy for "[a]n upward demand shift, produced by economic depression and war..." (p. 281) during 1921–1955. \overline{S} captures a 21-percent shift in (1) and so accounts for much of the variation in real per capita money, conditional on real per capita income. Figure 4 shows the fitted and actual values for $(\bar{m} - \bar{p} - \bar{n})$ derived from (1). Throughout, estimated standard errors are shown in parentheses (except in Table 1), $\hat{\sigma}$ is the standard deviation of the residuals [e.g., in (1), as a percentage of $\overline{M}/(\overline{PN})$], adjusted for degrees of freedom, and R^2 is the squared multiple correlation coefficient for the corresponding unweighted regression.⁵

Having replicated equation (a) by (1), we evaluate (1) against a range of alternative models. A summary of our approach is provided in Section III; here, we focus on the usual concerns of parameter constancy, price homogeneity, omitted variables, homoscedasticity, and normality. Once an empirical model has been formalized, then,

conditional on treating it as provisionally valid, many empirical phenomena are excluded. Consequently, a model is testable against the potential occurrence of such phenomena, *using tests that would be valid given the assumptions of that model*. The resulting tests have central distributions with approximately 5-percent critical levels under the null hypothesis of correct specification and noncentral distributions under their respective alternatives. Additionally, they may have power to reject alternatives other than those against which they were designed or have larger implicit than explicit null hypotheses (cf. Grayham Mizon and Richard, 1986).

Constancy is a major issue for money-demand equations (see John Judd and John Scadding, 1982), and Friedman and Schwartz regard their own U.K. money-demand equation as being constant: "[A] more sophisticated analysis [than the simple quantity theory] reveals the existence of a stable demand function for money covering the whole of the period we examine" (p. 624; see also pp. 7, 14, 64, 283). However, they do not formally *test* for constancy, and many investigators would regard the need for the data-based shift dummy \overline{S} spanning one-third of the sample as *prima facie* evidence against the model's constancy. Refitting (1) to the first half of the sample and predicting over the second half (doing each with *both* \overline{S} and \overline{W}), we tested for constancy using Gregory Chow's (1960 pp. 594–5) statistic: that yielded $\eta_1[18, 12] = 6.3$, which exceeds the 1-percent point of the F distribution. Although the one-step-ahead 95-percent confidence interval based on $\hat{\sigma}$ is larger than ± 11 percent, parameter nonconstancy can be detected, revealing an aspect about which the present data set is informative. The values of $\hat{\sigma}$ for the corresponding subperiods are markedly different: 2.8 percent and 6.0 percent, respectively. Even if these differences were due solely to heteroscedasticity, the inferences that Friedman and Schwartz draw from their regressions would be invalid because the t ratios are biased. Moreover, nonconstancy is not restricted to the residual variance. Figure 5 records the recursive estimates of

⁵Like those in Friedman and Schwartz, all our estimates using phase-average data are based on weighted least squares, correcting for the different phase lengths. However, parameter estimates are not very different whether ordinary or weighted least squares are used. All empirical calculations are from PC-GIVE (see Hendry, 1989).

FIGURE 4. EQUATION (1): ACTUAL AND FITTED VALUES FOR $(\bar{m} - \bar{p} - \bar{n})_j$ (THE TRANSFORMED REGRESSAND)

the interest rate coefficient from phases 16–36, together with a confidence region based upon plus-or-minus twice its estimated standard error at each sample size.⁶ As the sample size increases, the estimated coefficient changes substantially relative to its estimated uncertainty, with the final estimate lying outside the initial confidence interval. Such evidence refutes constancy in Friedman and Schwartz's reported model.

Since the dependent variable in (1) is $\bar{m} - \bar{p} - \bar{n}$, price homogeneity can be tested under two distinct maintained hypotheses about exogeneity, namely, whether M or P

is exogenous. Treating M as endogenous and relaxing unit price homogeneity in (1), we obtain

$$\begin{aligned}
 (2) \quad & \widehat{(\bar{m} - \bar{p} - \bar{n})}_j \\
 &= 1.01 + 0.68(\bar{i} - \bar{n})_j + 0.128\bar{p}_j \\
 &\quad (0.38) \quad (0.08) \quad (0.043) \\
 &\quad - 18.4\overline{RN}_j - 0.04G(\bar{p} + \bar{i})_j \\
 &\quad (3.8) \quad (0.26) \\
 &\quad + 1.05\overline{W}_j + 16.3\overline{S}_j \\
 &\quad (0.53) \quad (2.8)
 \end{aligned}$$

⁶In textbook notation, Figure 5 plots the i th coefficient and its estimated standard error: $\hat{\beta}_{ij} \pm 2\text{ESE}(\hat{\beta}_{ij})$, $j = 16, \dots, 36$, where $\hat{\beta}_j = (\mathbf{X}_j' \mathbf{X}_j)^{-1} \mathbf{X}_j' \mathbf{Y}_j$, $\mathbf{X}_j = (\mathbf{x}_1 \dots \mathbf{x}_j)'$, $\mathbf{Y}_j = (y_1 \dots y_j)'$, and $\text{ESE}(\hat{\beta}_{ij}) = \sqrt{\text{diag}_i[\hat{\sigma}_j^2 (\mathbf{X}_j' \mathbf{X}_j)^{-1}]}$. Under the null hypothesis of correct specification, $\hat{\beta}_{ij} \rightarrow \beta_i$ and $\text{ESE}(\hat{\beta}_{ij}) \rightarrow 0$ as $j \rightarrow \infty$ (see Andrew Harvey [1981 pp. 54–9] on the calculation of recursive least squares and associated test statistics and Kerry Patterson [1986] for an application). For annual data, the index j becomes t .

($J = 36$, $\hat{\sigma} = 5.03$ percent, $\text{dw} = 1.85$). The coefficient on \bar{p}_j is significant at the 99-percent level. If, instead, the exogeneity of M is maintained so that (1) purports to explain \bar{p}_j , then adding \bar{m}_j and \bar{n}_j to (1) to relax the homogeneity assumption yields $F_{[2,28]} = 20.56$, again rejecting the specification of (1).

FIGURE 5. EQUATION (1): RECURSIVE ESTIMATION OF THE COEFFICIENT ON \overline{RN}_j AND ITS ESTIMATED STANDARD ERROR

Next, to test for the absence of a trend, we estimate (3):

$$\begin{aligned}
 (3) \quad & \overline{(\bar{m} - \bar{p} - \bar{n})}_j \\
 & = -13.92 + 0.14(\bar{i} - \bar{n})_j \\
 & \quad (2.99) \quad (0.16) \\
 & -16.0\overline{RN}_j + 0.23G(\bar{p} + \bar{i})_j \\
 & \quad (2.7) \quad (0.24) \\
 & +1.80\overline{W}_j + 6.1\overline{S}_j + 0.0090\bar{i}_j \\
 & \quad (0.46) \quad (3.7) \quad (0.0019)
 \end{aligned}$$

($J = 36$, $\hat{\sigma} = 4.35$ percent, $dw = 1.99$). The coefficient on \bar{i}_j is statistically significant. By way of comparison, when Friedman and Schwartz tested for trends and price homogeneity in more restrictive models, they did not obtain rejections on this data set (pp. 253–9).

Although Friedman and Schwartz did not test for it, normality of the disturbances is also rejected: Carlos Jarque and Anil Bera's (1980) $\chi^2_{[2]}$ statistic for testing normality via

residual skewness and excess kurtosis is $\xi_3[2] = 6.9$ in (1).⁷ Testing the normality of the disturbances is of interest for two reasons. First, Friedman and Schwartz often base their statistical inferences on critical values of the F distribution (e.g., see pp. 232, 236), and given the small sample size ($J = 36$), those inferences may be affected substantively by nonnormal disturbances. Second, the Jarque-Bera statistic also has power against other alternatives, as suggested by it being insignificant when unit homogeneity of money with respect to prices is not imposed.

Taking this evidence together, equation (1) is not an adequate characterization of the data and is not consistent with the hypothesis of a constant money-demand equa-

⁷Given that the number of regressors fitted is often large relative to the sample size, we modify Jarque and Bera's (1980 p. 257) statistic to be $\xi_3[2] = [(J - k)/6] \cdot [\widehat{SK}^2 + \widehat{EK}^2/4]$, where SK and EK are skewness and excess kurtosis, respectively. $\xi_3[2]$ is asymptotically distributed as $\chi^2_{[2]}$ under the null hypothesis of normality, in which case $SK = EK = 0$.

tion, homogeneous of degree one in prices over the last century, even though Friedman and Schwartz state that "[t]his parallelism⁸ is a manifestation of the stable demand curve for money plus the excellence of the simple quantity theory approximation" (p. 7). The equations for nominal income and prices in Friedman and Schwartz were not further investigated because, as explained in Hendry and Ericsson (1985 appendix D), they are approximately renormalizations of their money-demand regression and so do not provide additional inferences (cf. pp. 344, 417). Additionally, any inferences based on (b)–(d) are hazardous because the split-sample Chow statistics for (b) and (c) are highly significant, and the Durbin-Watson statistics in (c) and (d) are less than the 5-percent lower bound.

When interpreting the outcomes of the above tests, four points should be borne in mind. First, the rejections are not mutually independent sources of information, since the implicit assumptions of any given test are shown to be invalid by the outcomes on other tests. Secondly, *none of the relevant hypotheses could have been tested by Friedman and Schwartz for this equation without their having obtained a rejection*. This shows the power of statistical evaluation to reveal the potential for model improvement and the ability of the data to discriminate between empirical models. Thirdly, discovering that their empirical model has a variety of specification problems has no implications for the existence (or otherwise) of a correctly specified empirical model of money demand being homogeneous in prices and having constant parameters. Finally, rejection of any null hypothesis does not imply that the alternative is correct. For example, constancy may have been rejected because of dynamic misspecification, and not because the underlying money-demand model has nonconstant parameters; or, in small samples, an F test could yield a misleading

outcome because of a highly nonnormal error distribution. These problems frequently arise in approaches that proceed by generalizing simple models (see Hendry, 1979).

Thus, we disagree with the methodology adopted by Friedman and Schwartz of basing many of their inferences on the analysis of simple empirical models:

Our ultimate objective is an explanation of the behavior of velocity, which is to say, of the quantity of money demanded, that takes account simultaneously of all the variables affecting velocity. Nonetheless, we believe that this ultimate objective is better approached indirectly, by examining variables one or two at a time, than by what has become the prevailing fashion in econometric work, the immediate computation of multiple regressions including all variables that can reasonably be regarded as relevant. We believe that the indirect approach yields insights that cannot be obtained from the more sweeping approach—that multiple correlations with many variables are almost impossible to interpret correctly unless they are backed by more intensive investigations of smaller sets of variables. Accordingly, we shall proceed in the following sections to consider variables one or two at a time, and reserve to section 6.7 estimating their simultaneous effect. [footnote:] The indirect approach played a critical role in the formulation of the multiple regressions that we calculate in section 6.7. . . . (p. 215)

This quote raises four methodological issues. First, the claim that simple models yield insights is frequently mistaken, since the associated measures of relationship and of uncertainty are misleading unless such models are coherent with the data. Secondly, it is incorrect to test hypotheses in one model and infer that the outcome will hold in generalizations of that model unless all the additional influences are orthogonal to those already included and remain so throughout the sample. Thirdly, although we concur that it is difficult to interpret

⁸Of nominal income and the nominal quantity of money, and of the rate of change of nominal income and the rate of change of the nominal quantity of money.

multiple regressions, this does not justify fitting misspecified submodels. Finally, the penultimate sentence of the above quote conflates the issues of estimation and modeling by seeming to imply that the only step remaining after examining the smaller sets is to estimate their joint effect: that would be true only if there were no interactions. The crucial issue is that a reject outcome at any stage of modeling invalidates *all previous inferences*, so that decision-taking during model generalizations is ill-founded. In Section III, we briefly describe an alternative methodology which resolves many of these issues and also reveals that there are other approaches to understanding general models. Moreover, a constructive empirical task remains to be undertaken, and we turn to that in Section IV, using the model developed by Friedman and Schwartz as a benchmark against which to compare other equations.

Before proceeding, we address the question of whether to use the annual observations or the phase-average data, the latter

being those which Friedman and Schwartz chose to analyze.

In order to isolate the longer-term relations that are our primary concern, we have converted our basic data, which are annual, into a form designed to be free from the shorter-term movements that are called business cycles. ... The device we have used to free the data from cyclical fluctuations is to take as our basic observation an average of annual observations over a cycle phase... (p. 13)

This device is taken from the NBER approach to business-cycle analysis, as documented by Arthur Burns and Wesley Mitchell (1946). Friedman and Schwartz argue that phase-averaging reduces serial correlation arising from the business cycle (p. 78) and attenuates measurement errors (p. 86). Doing so is important to sustain the validity of their statistical analyses, since, for example, no explicit account is made for biases in coefficient estimates and estimated

FIGURE 6. THE LOG OF THE VELOCITY OF MONEY: ANNUAL AND PHASE-AVERAGE DATA

standard errors resulting from residual autocorrelation. Friedman and Schwartz claim that phase-averaging successfully isolates longer-run behavior: "All in all, we conclude that our phase bases do eliminate the bulk of the systematic cyclical fluctuation" (p. 81).

The use of phase-average data raises three distinct issues: the theoretical statistical effects of phase-averaging (qua aggregation), the observed effects of phase-averaging on Friedman and Schwartz's data, and the impact of selecting the intervals over which to average by prior analysis of an interrelated data set. Julia Campos, Ericsson, and Hendry (1990) address these issues and show that (i) the aggregation from annual data to phase averages entails a loss of information by retaining only a subset of a previously averaged annual data set, (ii) phase-averaging does not materially reduce the serial correlation in Friedman and Schwartz's data, and (iii) phase-averaging involves a data-based set of filters but ignores the statistical consequences of such filters on later inferences. Figure 6 illustrates points (i) and (ii) for the time-series on velocity by jointly plotting v_t and \bar{v}_j . Neither the variance nor the autocorrelation of \bar{v}_j is notably smaller than that of v_t , whereas period-to-period changes in \bar{v}_j are much larger than those in v_t due to the observations being a phase rather than a year apart.

Thus, because of these unsatisfactory characteristics of phase-averaging, we analyze Friedman and Schwartz's original annual observations in an attempt to develop a money-demand equation that encompasses (1) and accounts for its failures. We next summarize the statistical framework and the associated theory of testing on which both the above analysis and the later models are based.

III. Econometric Modeling and Economic Theory

This section discusses the nature of empirical econometric models and serves as a guide to our uses of test statistics. Modeling is seen as an attempt to characterize data properties in simple parametric relation-

ships that are interpretable in light of economic knowledge, remain reasonably constant over time, and account for the findings of preexisting models. For general expositions of the associated methodology, see Hendry and Richard (1982, 1983), Hendry (1983, 1987), Hendry and Kenneth Wallis (1984), Ericsson and Hendry (1985), Christopher Gilbert (1986), and Aris Spanos (1986).

The formal methodology is based on the statistical theory of data reduction. Empirical models arise from *transformations* and *reductions* of the data generation process (DGP, a shorthand for the actual mechanism that generated the observed data), which is characterized by the joint density of the observable variables. The main steps producing models from the DGP are aggregation, algebraic transformation of data, marginalization, sequential conditioning, contemporaneous conditioning, truncation of lag length, and linearization. Each step entails a corresponding reduction and/or transformation of the parameters of the DGP to produce the reduced reparameterization in the econometric model. As a consequence, *all empirical models are derived entities*. Additionally, given the observed data and a formal model specification, the model's error process must contain everything in the data not explicitly allowed for by the model, and hence it also is derived rather than autonomous. This implies that models can be designed to satisfy preassigned criteria, as when residual autocorrelation is removed by a Cochrane-Orcutt transformation. While this example may be optimal in some circumstances, in others it entails invalid restrictions (cf. Hendry and Mizon, 1978).

The applied methodology distinguishes between the constructive and destructive roles of econometrics. The former corresponds to John Herschel's (1830) "context of discovery" and concerns issues of model design such as research efficiency. The latter is Herschel's "context of justification" and, for model evaluation, was illustrated in Section II. Criteria relevant to both design and evaluation are entailed by the conditions required to validate the (sometimes

implicit) sequence of reductions and transformations from which empirical models arise. Clearly, the validity of one-to-one data transformations is not an issue. However, reductions may entail a loss of information, and to judge that loss we use a taxonomy that partitions the universe of available information into disjoint sets: a) economic theory, the b) past, c) present, and d) future data of one's own model, e) the measurement system of the data, and f) the data of alternative models. These information sets generate the following criteria for design (in the context of discovery) and for evaluation (in the context of justification): A) theory consistency, B) innovation errors, C) weak

exogeneity, D) parameter constancy, E) data admissibility, and F) encompassing. A model is said to be *congruent* if it satisfies all of A–F and hence captures the salient features of the data and delivers reliable inferences on economic issues. Many of the criteria from A–F are standard and include the statistical and economic interpretation of estimated coefficients and the validity of a priori restrictions, goodness-of-fit and the absence of both residual autocorrelation and heteroscedasticity, valid exogeneity, predictive ability and parameter constancy, appropriate functional form, and the ability of a model to account for the properties of alternative models.

TABLE 2—CRITERIA FOR EVALUATING AND DESIGNING ECONOMETRIC MODELS

Null hypothesis	Alternative hypothesis	Statistic	Sources
B	first-order residual autocorrelation	dw	James Durbin and Geoffrey Watson (1950, 1951)
B	q th-order residual autocorrelation	$\xi_2[q];$ $\eta_2[q, T - k - q]$	George Box and David Pierce (1970); Leslie Godfrey (1978), Andrew Harvey (1981 p. 173)
B	q invalid parameter restrictions	$\eta_3[q, T - k - q]$	J. Johnston (1963 p. 126)
B	q th-order ARCH	$\xi_4[q]; \eta_4[q, T - k - 2q]$	Engle (1982)
B	skewness and excess kurtosis	$\xi_5[2]$	Jarque and Bera (1980)
B	heteroscedasticity quadratic in regressors (q quadratic terms)	$\eta_6[q, T - k - q - 1]$	White (1980), Desmond Nicholls and Adrian Pagan (1983)
B	q th-order RESET	$\eta_7[q, T - k - q]$	J. B. Ramsey (1969)
C	q instrumental variables not independent of errors	$\xi_8[q - k];$ $\eta_8[q - k, T - q]$	J. Denis Sargan (1958, 1964); Sargan (1980a p. 1136)
D	parameters not constant over subsamples	$\eta_9[k, T - 2k]$	R. A. Fisher (1922), Chow (1960 pp. 595–602)
D	predictive failure over a subset of q observations	$\eta_1[q, T - k - q]$	Chow (1960 pp. 594–5)

Notes: Null hypotheses correspond to criteria for design, as designated in the text. There are T observations and k regressors in the model under each null hypothesis. The value of q may differ across statistics, as may those of k and T across models and samples. $\xi_i[q]$ and $\eta_i[q, r]$ denote statistics that have central $\chi^2_{[q]}$ and $F_{[q, r]}$ distributions, respectively, under a common null and against the i th alternative. Thus, $\xi_2[q]$ and $\eta_2[q, T - k - q]$ both test for q th-order residual autocorrelation. We have labeled the Chow statistic $\eta_1[q, T - k - q]$ both to highlight the preeminence of the issue of constancy in the substantive debate on monetary behavior and because of its crucial role as an indirect test of weak exogeneity through testing the conjunction of hypotheses embodied in super exogeneity. The covariance test statistic $\eta_9[k, T - 2k]$ is often (and confusingly) referred to as the "Chow statistic" although Chow (1960 p. 592) was well aware of its presence in the literature.

In the context of discovery, satisfying a given criterion implies no loss of information from the associated reduction. In the context of evaluation, the criteria are interpretable as null hypotheses, and Table 2 summarizes the associated statistics. Since satisfying these criteria is a necessary condition for an empirical model to be congruent, failing any one of them is a sufficient condition for rejection. Conversely, since the route chosen for discovery cannot affect the *intrinsic validity* (or otherwise) of the finally selected model, issues of model design only concern the *efficiency* of alternative model-building strategies. Thus, we emphasize both explicitly *designing* empirical economic models to be congruent and rigorously *testing* the congruency of given model specifications. Since the latter takes models as formulated by their proprietors, the evaluative role of econometrics is not impugned by any of the current methodological debates (cf. Christopher Sims, 1980; Edward Leamer, 1983; Michael McAleer, Adrian Pagan, and Paul Volker, 1985; Hendry and Mizon, 1990). The failure to emphasize evaluation and testing is a major lacuna in Leamer's (1983) analysis, and our paper is a counterexample to the view that data evidence is not able to discriminate between alternative hypotheses. Rigorous evaluation of empirical claims seems a necessary first step toward taking the con out of economics, and indeed, Halbert White (1988) has shown that a sufficiently thorough testing procedure will arrive at a well-specified characterization of the DGP with confidence approaching certainty as the sample size grows without bound. The remainder of this section discusses the above criteria, their interrelationships, and their role in progressive research strategies.

A. Theory Consistency

Economic theory often suggests long-run relationships between economic variables, such as between two variables Y and Z (e.g., money and income) of the form $Y = KZ$ where K is a constant. In logs, that theory becomes $y = \kappa + z$ with $\kappa = \ln(K)$. *Cointegration* links the economic notion of a

long-run relationship between variables with a statistical model of those variables.⁹ For convenience, we adopt the time-series notation that a nonstationary variable integrated of order d [i.e., $I(d)$] requires differencing d times to make it stationary [i.e., $I(0)$]. For $I(1)$ variables y_t and z_t , arbitrary linear combinations $y_t + \delta z_t = u_t$ are also $I(1)$. If a value of δ exists such that u_t is $I(0)$, then y_t and z_t are "cointegrated" and so do not drift too far apart (e.g., because of agent behavior). Proportionality between Y and Z implies $\delta = -1$. Cointegration of y_t and z_t can be tested by testing for the absence of a unit root in u_t , that is, whether u_t is $I(0)$ rather than $I(1)$, with $I(0)$ being necessary for theory consistency.

B. Innovation Errors

Dynamic specification influences model design because of the statistical and economic importance of (white-noise) innovation errors. As a rule, dynamic misspecification invalidates inference, so dynamics cannot be safely ignored. There are many possible dynamic formulations for economic models (e.g., see Hendry, Pagan, and J. Denis Sargan, 1984); but since cointegration implies and is implied by the existence of a (dynamic) error-correction representation of the relevant variables, we consider the properties of and intuition behind error-correction models (cf. Sargan, 1964; James Davidson et al., 1978 pp. 679–82; Mark Salmon, 1982). For expositional simplicity, suppose that only the current values of y and z and their one-period lags matter, that y and z are cointegrated, and that the relationship is linear, in which case

$$(4) \quad y_t = \alpha + \alpha_1 y_{t-1} + \beta_0 z_t + \beta_1 z_{t-1} + \nu_t$$

$$\nu_t \sim \text{IN}(0, \sigma_\nu^2)$$

where IN means "is distributed indepen-

⁹See Clive Granger (1981), Hendry (1986), Engle and Granger (1987), Jeff Hallman (1987), Peter Phillips (1987), and James Stock (1987). Engle (1987) and Juan Dolado and Tim Jenkinson (1987) survey the literature.

dently normally." In (4), long-run homogeneity between y and z requires that $\alpha_1 + \beta_0 + \beta_1 = 1$. Rewriting the autoregressive-distributed lag relationship in (4) by imposing that restriction gives

$$(5) \quad \Delta y_t = \alpha + \beta \Delta z_t + \gamma(y_{t-1} - z_{t-1}) + \nu_t$$

where α , β , and γ are the corresponding *unrestricted* parameters.¹⁰ Intuitively, the term $\beta \Delta z_t$ reflects the immediate effect of a change in z_t on y_t . The term $\gamma(y_{t-1} - z_{t-1})$ (with γ negative for dynamic stability and, therefore, cointegration) is statistically equivalent to having $\gamma(y_{t-1} - \kappa - z_{t-1})$ instead, and hence reflects the effect on Δy_t of having y_{t-1} out of line with $\kappa + z_{t-1}$. Such discrepancies could arise from errors in agents' past decisions, with the presence of $\gamma(y_{t-1} - z_{t-1})$ reflecting their attempts to correct such errors; so, (5) belongs to the class of *error-correction* models (ECM's).¹¹ For a steady-state growth rate of Z_t equal to g (i.e., $g = \Delta z_t = \Delta y_t$) and $\nu_t = 0$, then solving (5), we have

$$(6) \quad Y_t = Z_t \exp\{[-\alpha + g(1 - \beta)]/\gamma\}$$

which reproduces the nonstochastic steady-state theory of proportionality between Y_t and Z_t . This example is readily extended to include further lags, nonproportionality, and nonlinearity, and so is representative of a large class of models that satisfy steady-state economic-theoretic restrictions and allow for general dynamic responses.

The choice of normalization of the cointegrating vector is an unresolved issue, but both economics and the data can help. Theory may suggest which variables agents aim to control and on which ones they condition their plans; and as parameter constancy in an empirical model is *not* invariant to nor-

malization when the economy exhibits structural change, data can preclude some choices. Thus, normalization and conditioning both lead to the next two issues: exogeneity and parameter constancy.

C. Weak Exogeneity

The four distinct concepts of exogeneity (weak, strong, super, and strict), discussed by Engle et al. (1983), correspond to different notions of being "determined outside the model under consideration" according to the purposes of the inferences being conducted (i.e., conditional inference, prediction, policy analysis, and forecasting, respectively).¹² In no case is it legitimate to "make variables exogenous" simply by not modeling them. Weak exogeneity can occur when agents act contingently on available information. If agents use that information efficiently, innovation errors are implied, relating back to the issue of dynamic specification. Weak exogeneity is testable, often as an implication of super exogeneity (and so of models having constant parameters). Section IV further discusses exogeneity in the context of the empirical model.

D. Parameter Constancy

Parameter constancy is at the heart of model design from both statistical and economic perspectives. Since economic systems are far from being constant and the coefficients of derived ("nonstructural" or "reduced form") equations may change when any of the underlying parameters or data correlations change, it is important to identify empirical models that have reasonably constant parameters, which remain interpretable when change occurs. As seen in Section II above and Section IV below, recursive estimation provides an incisive tool for investigating parameter constancy, both through the sequence of estimated coeffi-

¹⁰With the lag operator L defined as $Lx_t = x_{t-1}$, we let the difference operator Δ be $(1 - L)$; hence, $\Delta x_t = x_t - x_{t-1}$. More generally, $\Delta^q x_t = (1 - L)^q x_t$. If q (or r) is undefined, it is taken to be unity.

¹¹Alternatively, Stephen Nickell (1985) justifies error-correction mechanisms as arising from the optimal response of economic agents in some dynamic environments.

¹²This formulation is also discussed in Jean-Pierre Florens and Michel Mouchart (1985a, b) and builds on Tjalling Koopmans (1950) and Ole Barndorff-Nielsen (1978).

391
001

P 7831

cient values and via the associated Chow statistics for constancy.¹³ The Chow statistics also play crucial roles for testing weak exogeneity indirectly through testing the conjunction of hypotheses embodied in super exogeneity and for testing feedback versus feedforward empirical models (cf. Engle et al., 1983; Hendry, 1988).

E. Data Admissibility

Many economic variables are inherently positive, a model property ensured by the use of logarithmic transformations of the data. However, if the resulting model does not correspond to the DGP, the cost of enforcing data admissibility may be a loss of parameter constancy.

F. Encompassing

This concept can be understood intuitively as follows. Suppose model 1 predicts $\hat{\theta}$ as the value for the parameter θ in model 2, while model 2 actually has the estimate $\hat{\theta}$. Model 1 encompasses model 2 if $\hat{\theta}$ is "statistically close" to $\hat{\theta}$, so that model 1 explains why model 2 obtains the results it does. To the extent that model 1 accurately mimics the DGP, it will encompass model 2. For single equations estimated by least squares, a necessary condition for encompassing is *variance dominance*, where one equation variance-dominates another if the former has a smaller error variance.¹⁴ Thus, encompassing is more demanding than selecting models purely on the basis of their goodness of fit. It is also consistent with the concept of a progressive research strategy (e.g., see Imre Lakatos, 1970; Alan

Chalmers, 1976), since an encompassing model is a "sufficient representative" of previous empirical findings.¹⁵

These six criteria not only characterize the conditions required to sustain reductions, they also correspond to concepts central to econometric analysis. Taking the reductions in turn, a set of current-dated variables can be eliminated (marginalized) without loss of information if those retained correspond to *sufficient statistics*, and lagged variables can be marginalized if they do not *Granger-cause* the remaining variables. Sequential conditioning generates *innovation errors*, and contemporaneous conditioning is valid if the variables so treated are weakly *exogenous* for the parameters of interest. The concept of *encompassing* introduced above determines the limits to model reduction (i.e., the degree of *parsimony* feasible). As shown in Hendry and Richard (1989), parsimonious encompassing (in which the smaller model accounts for the results of a larger model within which it is nested) is transitive, antisymmetric, and reflexive, thus defining a partial ordering over models and thereby sustaining a progressive research strategy.

IV. Econometric Modeling of Money Demand Using the Annual Data

This section develops a conditional econometric model of money demand on the annual data series for 1878–1970 only ($T = 93$), since the data from 1971 to 1975 appear to have a different stochastic structure [see (11) below]. We follow the procedures outlined in Section III, representing the joint density of $(m_t, p_t, i_t, RS_t, RL_t)$ in terms of an autoregressive-distributed lag model for m_t conditional on (p_t, i_t, RS_t, RL_t) and a marginal model for (p_t, i_t, RS_t, RL_t) . The conditional model is simplified to an ECM and evaluated in light of

¹³These tests of constancy are intimately related to tests of forecast accuracy (cf. R. Brown, Durbin, and J. M. Evans, 1975; Hendry, 1979; Jan Kiviet, 1987). Jean-Marie Dufour (1982) elegantly summarizes recursive techniques and their implications.

¹⁴Formally, variance dominance refers to the underlying (and unknown) error variances. Without loss of clarity, we often will say a model variance-dominates another if the *estimated residual* variance of the former is smaller than that of the latter.

¹⁵For comprehensive accounts of tests for encompassing and of related nonnested hypothesis tests, see Mizon and Richard (1986), Mizon (1984), James MacKinnon (1983), and Hashem Pesaran (1982).

the model design criteria.¹⁶ Phillips (1988) and Phillips and Bruce Hansen (1990) demonstrate that this error-correction approach produces nearly optimal inferences in cointegrated processes. Such a methodology of "learning from the data" while being guided by economic theory in the interpretation of results contrasts with the approach adopted by Friedman and Schwartz of using regression results to corroborate their economic theory. We conclude this section by considering two important issues for economic policy: the constancy of the money-demand function and the exogeneity of money.

The economic framework of our empirical model is that of a log-linear long-run money-demand function:

$$(7) \quad (m - p)^* = \delta_0 + \delta_1 i - \delta_2 RS - \delta_3(1 + \dot{p})$$

where an asterisk denotes the long-run target value and \dot{p} is the rate of inflation (cf. Friedman, 1956). Equation (7) parallels the condition $y = \kappa + z$ in Section III-A. Dynamic adjustment is characterized by a contingent planning model of the form

$$(8) \quad \Delta(m - p)_t = \lambda_0(L)\Delta(m - p)_{t-1} + \lambda_1(L)\Delta p_t + \lambda_2(L)\Delta i_t + \lambda_3(L)\Delta rs_t + \lambda_4(L)\Delta rl_t + \lambda_5[(m - p)_{t-1}^* - (m - p)_{t-1}] + \varepsilon_t$$

where $\lambda_i(L)$ ($i = 0, \dots, 4$) denotes a finite polynomial in the lag operator L and ε_t is the deviation of the outcome from the plan. This approach generalizes the conventional partial-adjustment model, allowing separate reaction speeds to the different determi-

nants of money demand (reflecting potentially different costs of adjustment and of disequilibrium), yet via the error-correction mechanism ensures that long-run targets are achieved (e.g., velocity and interest rates are cointegrated) (cf. Hendry et al., 1984). Economically, (8) is related to the theory of money adjustment in Merton Miller and Daniel Orr (1966) and Ross Milbourne (1983), in which the short-run factors determine money movements *given* the desired bands, and the longer-run factors influence the levels of the bands (e.g., see Gregor Smith, 1986). To be interpretable as a demand equation, $\lambda_1(1) \leq 0$, $\lambda_2(1) \geq 0$, $\lambda_3(1) \leq 0$, and $\lambda_4(1) \leq 0$; and for cointegration, $\lambda_5 < 0$. However, the choice of parameterization (e.g., in terms of lagged first differences or higher-order differences) is arbitrary *within* lag polynomials, so no sign restrictions on individual polynomial coefficients can be imposed a priori. Moreover, since monetary theory does not yet specify how quickly agents react to changes in real time, the orders of the $\lambda_i(L)$ must be data-based.

Statistically, (8) is an ECM reparameterization of an autoregressive-distributed lag model of the variables in levels, as is (5) of (4). A model such as (8) is of interest only if the regressors are weakly exogenous for the resulting parameters, which in turn must be constant and invariant to historical changes in the processes determining the marginal distributions. The error in (8) will be an innovation if the plan efficiently incorporates available information and the model is correctly specified. All of these issues are examined below in order to discriminate between contingent planning and expectations interpretations of the empirical model.

In Hendry and Ericsson (1983), we presented an autoregressive-distributed lag representation of money conditional on prices, incomes, and interest rates to establish the innovation error variance. That formulation was simplified to an ECM like (8) based on extant money-demand models for the United Kingdom, with a static-equilibrium solution of the form $v = -\delta_0 + \delta_2 RS$ (thus taking v_t and RS_t to be cointegrated) and an equation standard error of

¹⁶See Hendry and Mizon (1978) and McAleer et al. (1985) on modeling from general to simple; see Leamer (1978) for an analysis of specification searches.

TABLE 3—A GENERAL AUTOREGRESSIVE-DISTRIBUTED LAG REPRESENTATION FOR MONEY (m_t),
CONDITIONAL ON INCOMES, PRICES, AND INTEREST RATES

Variable	lag i (or index)						$\Sigma_{i=0}^5$

\hat{u}_{t-1}^i		0.077 (0.092)	0.485 (0.204)	-1.821 (1.285)			
D_i		3.993 (1.220)	0.607 (1.751)	3.624 (1.024)			
Constant	-0.201 (0.137)						

Notes: Values in parentheses are estimated standard errors; $T = 1878-1970$, $R^2 = 0.99987$, $\hat{\sigma} = 1.5535$, $dw = 1.94$, $\xi_2[11] = 9.62$, $\eta_2[3, 54] = 0.46$, $\eta_4[4, 49] = 1.39$, $\xi_5[2] = 1.01$, $\eta_6[39, 17] = 0.23$, $\eta_7[2, 55] = 1.28$. For readability, coefficients and estimated standard errors on D_1 , D_2 , and D_3 are multiplied by 100.

1.71 percent of M .¹⁷ Those results stimulated further studies, including an improved specification on the same information set in Andrew Longbottom and Sean Holly (1985), a nonlinear reformulation in Alvaro Escribano (1985), and an extended information set for 1875-1913 in Jan Klovland (1987).¹⁸ Longbottom and Holly's and Escribano's models were significant improvements on our 1983 model (i.e., each of their models encompassed ours, but ours could not encompass either of theirs). However,

¹⁷Hendry and Ericsson (1985) investigate the hypothesis that v_t is a random walk and conclude that there is little contrary evidence. Likewise, the data on m , i , p , $m-p$, rs , rl , and p^* all behave like $I(1)$ series, whereas their corresponding first differences behave like $I(0)$ series. Nevertheless, equations (9) and (10) show that a more general cointegrating relationship can be established.

¹⁸Klovland (1987) constructs a new measure of the own interest rate on M .

neither of their models could encompass certain features of the other, indicating that an improved specification might be possible.

Continuing in a progressive research strategy, we utilize their (and our previous) evidence, beginning with the static cointegration regression for v_t and RS_t :

$$(9) \quad (\overline{m-i-p})_t = -0.309 - 7.00RS_t$$

($T = 1873-1970$, $R^2 = 0.56$, $\hat{\sigma} = 10.86$ percent, $dw = 0.33$, $ADF(1) = -2.77$). (Adding RL makes little difference, unsurprisingly if RS and RL are cointegrated.) Exact significance levels are not available for David Dickey and Wayne Fuller's (1979, 1981) augmented statistic $ADF(1)$ or for Sargan and Alok Bhargava's (1983) Durbin-Watson-based statistic when testing for a unit root in the residuals, but the 10-percent critical values in Engle and Granger (1987), based on simulation, are respectively -2.84

and 0.32 for 100 observations, leading to an inconclusive outcome. Engle and Granger (1987) show that these tests have low power against highly dynamic stationary alternatives, so we cautiously proceed under the assumption of cointegration. Economically, the solution to (9) is within the framework of (7) and implies that a one-percentage-point increase in the short-term interest rate (e.g., from 5 percent to 6 percent) reduces M relative to PI by 7 percent in the long run.

Cointegration implies an error-correction representation, so to model the behavior of money we estimate an unrestricted fifth-order autoregressive-distributed lag equation related to (4); it is shown in Table 3 together with relevant test statistics.¹⁹ The model in Table 3 generalizes on (4) by inter alia allowing the speed of adjustment to vary with the extent of disequilibrium via nonlinear error-correction terms. Following Escribano (1985), Table 3 includes the lagged level, square, and cube of \hat{u}_t , the residual from (9). Three zero-one dummies (D_1 , D_2 , and D_3), which are unity for 1914–1918, 1921–1955, and 1939–1945, respectively, also appear. This regression satisfies all of the diagnostic checks reported and provides generally sensible estimates, despite very high intercorrelations between regressors. Most coefficients of lags beyond three are negligible as well as insignificant, and deleting those lags lowers $\hat{\sigma}$. The entailment static solution is consistent with long-run price and income elasticities of around unity.

The representation in Table 3 was simplified to the error-correction model (10) using the approach described in Hendry (1983) of first transforming the model to an interpretable and near orthogonal specification paralleling (8) and then eliminating negligi-

ble and insignificant effects:

$$\begin{aligned}
 (10) \quad & \overline{\Delta(m-p)}_t \\
 & = 0.45 \Delta(m-p)_{t-1} \\
 & \quad [0.06] \\
 & \quad - 0.10 \Delta^2(m-p)_{t-2} \\
 & \quad [0.04] \\
 & \quad - 0.60 \Delta p_t + 0.39 \Delta p_{t-1} \\
 & \quad [0.04] \quad [0.05] \\

($T = 1878-1970$, $R^2 = 0.87$, $\hat{\sigma} = 1.424$ percent, $\eta_2[6, 78] = 1.56$, $\eta_3[27, 57] = 0.50$, $\eta_4[4, 76] = 1.24$, $\xi_5[2] = 1.6$, $\eta_6[15, 68] = 0.87$, $\eta_7[2, 82] = 0.21$; see Table 2 for definitions of the statistics). Values in brackets are heteroscedasticity-consistent estimated standard errors (see White, 1980; Desmond Nicholls and Pagan, 1983; MacKinnon and White, 1985).

Concerning its economic interpretation, (10) is similar in form and in numerical parameter values to several successful money-demand models for the United Kingdom (cf. Hendry and Mizon, 1978; Hendry, 1979; John Trundle, 1982; Davidson, 1987; Keith Cuthbertson, 1988). Its coefficients satisfy the sign restrictions on the $\lambda_t(1)$ in (8) to be interpretable as a money-demand function. The coefficients' sizes imply large immediate responses to changes in inflation and interest rates but slow adjustment subsequently to remaining disequilibria, via the error-correction term. Inflation enters as $\Delta p_t + \Delta^2 p_t$ (approximately), which is a predictor of next period's inflation, optimal if prices vary quadratically. Thus, (10) has a forward-looking interpretation, albeit one based on *data functions* rather than on

¹⁹We have chosen five lags on the grounds that this implies 36 parameters estimated in Table 3 (vs. 93 observations total), in line with guidelines in Sargan (1980b p. 880). Also, five lags implies a maximum lag of approximately one cycle.

FIGURE 7. EQUATION (10): ACTUAL AND FITTED VALUES FOR $\Delta(m-p)_t$

models of the right-hand-side variables.²⁰ The coefficients correspond to nearly orthogonal decision variables (with only two of the 28 regressor intercorrelations exceeding 0.5), consistent with (10) representing a contingent plan of agents who partition available information into conceptually separate entities.

The empirical parameterization in (10) exhibits multiple equilibria, with two corresponding to the long-run solution (9) and a third being that solution shifted by 20 percent. In that sense, the results are consistent with the use of an adjustment factor of about that order by Friedman and Schwartz. However, the dating of the disequilibria is determined by the values of \hat{u}_{t-1} and operates over the entire sample, not just for the period 1921–1955.

Concerning the statistical attributes of (10), the various diagnostic checks are in-

significant (if regarded as test statistics) and indicate design of a model congruent with the information available. Even so, the range of alternatives considered is sufficiently large to endow (10) with some credibility. From η_2 , the residuals are white noise and, from η_3 , are also an innovation process against the information set in Table 3. There is no ARCH, RESET, or heteroscedastic evidence of misspecification; the residuals are approximately normally distributed; and (10) encompasses our earlier models and those of Escobano and of Longbottom and Holly (but not conversely).²¹ Figure 7 shows the

²⁰Campos and Ericsson (1988) propose this interpretation for similar inflation terms entering an equation for consumers' expenditure in Venezuela.

²¹By appropriately (statistically) reducing the density for our model, one could derive an estimate of the parameters in Friedman and Schwartz's model. From that constructed estimate and the estimate they actually obtain, one could test whether our model (using annual data) encompasses theirs (using phase-average data). Note also that it is easy to construct examples for which the parameters in their model would not be constant over time but those in ours would be [e.g., the parameters in (10) are constant, p_t is Granger-caused by m_t , and the coefficients in that price equation change over time]. Existence of the converse would

actual and fitted values for the rate of change in real money over the sample period. Visual comparison of Figures 4 and 7 (noting the logarithmic scale in both) highlights the better fit of the annual model: the error variance of (10) is less than one-tenth of that in (1). Although (10) has a rate of change as the dependent variable, it is an equation in log-levels because of the error-correction term, as shown in (4)–(5) above, so direct comparison of the two graphs is valid.

The two remaining issues are constancy and exogeneity. Any claim to the constancy of a model for money demand would need both constant parameters and a similar goodness of fit over each of the epochs described above for Figure 1; in Section II, we demonstrated that (1) has neither.²² To investigate the constancy of our model (10), we adopt the recursive estimator, since the one-step innovations allow the construction of sequences of constancy tests. Given the world wars dummy ($D_1 + D_3$), 1915 is the earliest date for a continuous sequence until 1970, although a separate exercise is possible for the subsample 1878–1913 (see Fig. 11, below). Graphical presentation is efficient for reporting the large volume of evaluation output: Figure 8 records the one-step residuals and the corresponding calculated equation standard errors (i.e., $y_t - \hat{\beta}'_t x_t$ and $0.0 \pm 2\hat{\sigma}_t$ in a standard notation). *It is visually apparent that $\hat{\sigma}$ has varied little over the 56-year test period.* Further, none of the Chow statistics for the sequence 1915, 1915–1916, 1915–1917, ..., 1915–1970 or the sequence 1915–1970, 1916–1970, 1917–1970, ..., 1969–1970, 1970 is significant at even the 5-percent level. Figures 9

and 10 show the numerical values of two central coefficients, namely, those for Δp_t and the error-correction $(\hat{u}_{t-1} - 0.2)\hat{u}_{t-1}^2$, together with plus-or-minus twice their sequentially estimated standard errors, which provide an approximate 95-percent confidence interval.²³ Other than a minor fluctuation directly following World War I, the former varies by only a tiny fraction of its *ex ante* standard error; the latter is highly significant for the entire sample and also varies little relative to the estimated uncertainty. In both cases, the accrual of information is apparent from the reduction in the width of the confidence interval over time. Figure 11 graphs the one-step residuals for 1892–1913, using only 15 observations to initialize estimation; not only is $\hat{\sigma}$ constant, but its value throughout is very close to that for the full sample. In brief, our *conditional* reformulation both fits well and is constant over the century to 1970, even though the time-aggregated phase-average data reveal the nonconstancy of (1) despite the attendant loss of information.

Thus, we reach the issue of the exogeneity of money. Our analysis has taken every contemporaneous variable other than m as if it were weakly exogenous (i.e., that it is valid to condition upon them for purposes of statistical inference), interpreting the coefficients of the resulting model as those of a money-demand equation; by construction, (10) is *invariant* to whether Δm_t or $\Delta(m - p)_t$ is the regressand. The constancy of (10) reinforces our interpretation, which is also consistent with the institutional structure of U.K. money markets in which the money stock appears to be endogenously determined by the decisions of the private sector since the Bank of England in effect acts as a lender of the first resort by standing ready to rediscount first-class bills at the going Bank Rate or Minimum Lending Rate (see e.g., R. Hawtrey, 1938; Congdon, 1983; Goodhart, 1984). Its constancy suggests that the conditioning variables may be super ex-

immediately refute any claim to encompass their findings.

²²A possible objection might be that a money-demand equation's "constancy" need not be precise but only relatively better than (say) the consumption function's constancy. Since Friedman and Schwartz assert that their model is indeed constant, such an objection is not germane. However, in response to Mayer (1982 p. 1534), we note that the U.K. consumption function was investigated in Hendry (1983) and was shown to be remarkably constant both before and after World War II.

²³Note, however, that the coefficients within \hat{u}_{t-1} are full-period estimates, as justified by the distributional results in Engle and Granger (1987).

ogenous for the demand parameters over the sample (i.e., that the parameters of the conditional model remain constant even though the DGP of the conditioning variables changes over the sample). The exogeneity of prices and endogeneity of money are substantive issues, noting that it is commonplace in macroeconomics to determine prices via the money-demand equation, taking income, interest rates, and an observed money supply as given and equating supply to demand (cf. Robert Barro, 1987 pp. 128–31, 195–210). In particular, the empirical super exogeneity of prices (shown below) invalidates “inverting” the money-demand equation to obtain prices. Engle and Hendry (1989) show that several implications of super exogeneity are testable.

First, direct tests of super exogeneity can be constructed, but they require additional observables, the relevance of which to (10) is that those observables should not have been used in model design [e.g., none of the variables dropped in simplifying from Table 3 to (10) would give the tests power]. For these data, the crucial issue is the weak exogeneity of Δp_t , since, if that is accepted, (10) cannot sustain the interpretation of determining prices with money exogenous. The additional instruments we have tried are a trend and current and lagged U.S. inflation (Δp_t^* and Δp_{t-1}^*), using a recursive instrumental variables estimator to investigate constancy and exogeneity conjointly (see Hendry and Adrian Neale, 1987). On endogenizing Δp_t , $\hat{\sigma}$ remains virtually unchanged at 1.44 percent, and Sargan’s (1958) statistic for testing the validity of the instruments yields $\xi_8[2] = 3.62$, justifying the choice of instruments and being consistent with the weak exogeneity of Δp_t .²⁴ More-

over, the demand equation is constant despite the manifest nonconstancy of the instrumenting equation (cf. Fig. 12), revealing how informative this data set is and precluding a forward-looking expectations interpretation of (10) (cf. Hendry, 1988).²⁵

Second, super exogeneity is not invariant to alternative factorizations of the joint density of money and prices when parameters in that density are not constant over time. That is, if the model (10) were inverted to make Δp_t the regressand, conditional on Δm_t , as an exogenous variable, then the resulting equation should be nonconstant. This is the case, as seen in Figure 13, which records the behavior of the estimated coefficient of Δm_t in the inverted equation. Further, the equation standard error becomes 2.6 percent and, unlike (10), the inverted equation cannot encompass the simple model that Δp_t^* determines Δp_t through a purchasing power parity condition: $\eta_3[1, 83] = 14.9$.

This evidence is inconsistent with the hypothesis that, over the period 1878–1970, exogenous money determined prices in the United Kingdom via a stable money-demand function, *precisely because we have established a constant money-demand model conditional on prices*. In Hendry and Ericsson (1986), we propose an alternative mechanism for money causing inflation: namely, the long-run effects of deviations from purchasing-power parity.

The final test of super exogeneity is that the parameters are invariant to regime changes: here, we exploit the joint introduction of floating exchange rates and Compe-

²⁴We also investigated the assumed *joint* weak exogeneity of prices and short- and long-term interest rates in (10). (The weak exogeneity of income is not at issue because it appears only at a lag, via the error-correction term.) When estimated with Δp_t^* , Δp_{t-1}^* , rs_{t-1} , rs_{t-2} , rl_{t-1} , rl_{t-2} , and a trend as instruments and treating $\Delta(m-p)_t$, Δp_t , Δrs_t , and $\Delta_2 rl_t$ as endogenous, $\hat{\sigma}$ increases only slightly to 1.56 percent, the coefficients remain virtually unchanged from (10), and Sargan’s (1958) statistic is $\xi_8[4] = 4.96$ (insignificant). Further, estimation of the reduced-form equations for

Δp_t , Δrs_t , and $\Delta_2 rl_t$ by recursive multivariate least squares reveals nonconstancy in each. If there were simultaneity bias in (10), the parameter estimates in (10) would change as those in the reduced-form equations did; thus, the *constancy* of (10) in spite of nonconstant reduced-form equations implies the weak exogeneity of prices and interest rates. See Hendry, Neale, and Srba (1988) on recursive multivariate least squares, and see Jean Bronfenbrenner (1953) on the relationship between simultaneity bias and reduced-form parameters.

²⁵See Engle (1984) for a survey of exogeneity tests and Kiviet (1985, 1987) for finite-sample evidence on their performance.

FIGURE 12. ONE-STEP RESIDUALS FROM THE INSTRUMENTING EQUATION FOR Δp_t USING Δp_t^* FIGURE 13. RECURSIVE ESTIMATION OF THE COEFFICIENT ON Δm_t IN THE INVERTED MODEL FOR Δp_t USING (10)

tion and Credit Control regulations in 1971. Narrow money demand (U.K. M_1 measure) apparently was not perturbed by these switches, but most investigators have found major parameter changes in models of broad money measures (e.g., U.K. $\text{£}M_3$; see Hendry and Mizon [1978] and Michel Lubrano, Richard Pierse, and Richard [1986] for overviews). A Chow test of (10) using predictions over 1971–1975 yields $\eta_1[5, 84] = 19.5$, and $\hat{\sigma}$ rises to 2.03 percent, rejecting constancy and super exogeneity. The growth rate of nominal money over this test period substantially exceeds that of any previous episode (including both world wars) and could reflect a disequilibrium adjustment to the removal of the chronic cartelization of the U.K. banking system (the motivation for the change in banking regulations). Indeed, Lubrano et al. (1986) find that the long-run relationship of money demand to prices and incomes holds after 1970 but that the short-run relationship is severely perturbed, with money demand *increasing* as competitive interest rates increase. With that structure in mind, we obtained

$$\begin{aligned}

 \end{aligned}$$

($T = 1878-1975$, $R^2 = 0.88$, $\hat{\sigma} = 1.478$ percent, $\eta_2[6, 81] = 1.19$, $\eta_4[2, 83] = 1.31$, $\xi_5[2] = 2.9$, $\eta_6[18, 68] = 0.43$), where D_4 is a dummy which is unity over the period 1971–1975

and zero otherwise, and where \hat{u}_{t-1} is still calculated from (9). Now $\hat{\sigma}$ and most of the coefficients other than those involving D_4 are virtually unaltered, consistent with Lubrano et al.'s results.

A potential explanation for this finding, consistent with the earlier evidence and economic analysis, is presaged by Klovland's (1987) result for pre-1914 data that the *own* interest rate on broad money is an important omitted variable from the present information set.²⁶ Over much of the sample, U.K. commercial banks acted like a cartel with administered (and generally low) deposit interest rates; this situation changed after 1970 due to the competition regulations. Thus, own interest rates rose rapidly, altering the historical differentials and inducing predictive failure in models that excluded that variable. We plan to extend Klovland's data set to test this conjecture and to continue the progressive research strategy by encompassing previous models.

V. Conclusions

This paper focuses on the evaluation of Friedman and Schwartz's (1982) empirical model for U.K. money demand and the design of an improved specification using their annual data. At the heart of model evaluation are the issues of model credibility and validity and the role of corroborating evidence. The failure by Friedman and Schwartz to present statistical evidence pertinent to their main claims about the United Kingdom leaves those claims lacking in credibility. The presence of substantial misspecification invalidates many of their infer-

²⁶In Hendry and Ericsson (1983 pp. 77–8), we experimented with RS replaced by RN, Friedman and Schwartz's (1982 p. 270) measure of the marginal cost of money [$RN \equiv RS \cdot (H/M)$]. The resulting estimates are very similar to those found using RS and reveal no improvement in the constancy of the interest-rate coefficient over 1971–1975. Following suggestions by Chris Pissarides and by Ross Starr (1982), we also experimented with adding variables that measured interest-rate volatility (e.g., using $0.2\sum_{i=0}^4 [RS_{t-i} - RS_t^*]^2$ where $RS_t^* = 0.2\sum_{i=0}^4 RS_{t-i}$). The effect was largest for the most recent period but did not produce constant parameters or a constant fit over 1971–1975.

ences from equations based on the phase-average data (cf. Table 1). In particular, their final money-demand equation is not constant, contrary to their claim; and, on testing assumptions such as price homogeneity and the absence of trends, rejection results. Such negative findings are consistent with those reported by Meghnad Desai (1981 [especially Ch. 4]). The procedure of averaging data over business-cycle phases did not notably reduce the serial correlation in the data series but did lose information, leading to rather badly fitting equations. As an alternative, we recommend analyzing the annual data and modeling "trend" and "cycle" jointly.

Corroborating a subset of the implications of a theory is not by itself an adequate justification for deeming the theory useful (see e.g., Friedman, 1953 pp. 8–9; Karl Popper, 1959 section 82; Lawrence Boland, 1982 Ch. 1). That is illustrated by the contrast between Friedman and Schwartz's claims to have empirically corroborated various aspects of their theories and our evidence that those claims are actually refutable from the same data. Only well-tested theories that have successfully weathered tests outside the control of their proponents and that encompass the gestalt of existing empirical evidence seem likely to provide a useful basis for applied economic analysis and policy.

The tests used to evaluate Friedman and Schwartz's models indicate that scope exists for model development but do not indicate what changes are required. We attempted an improved specification and presented an econometric model of the demand for money in the United Kingdom during 1878–1970 which incorporates economic theory, satisfies a wide range of statistical criteria, and encompasses existing models based on the same data set. Those features are essential for a model to characterize the underlying data generation process adequately. On a substantive level, the empirical constancy of our model is consistent with a structure in which nominal money is endogenously determined by demand factors, conditional on prices, incomes, and interest rates. Undoubtedly, the model pro-

posed above is not the end of the story since, for example, parameter nonconstancy is evident during 1971–1975. That it is not perfect is less than surprising, as the data span a century during which financial institutions altered dramatically: witness the growth of building societies and, after 1970, the introduction of Competition and Credit Control regulations and of floating exchange rates. Even so, the evidence suggests that substantial benefits are available in practice from a progressive research strategy exploiting tests in both model design and model evaluation.

DATA APPENDIX

Legend

D_1	A dummy variable for World War I (= 1 for 1914–1918 inclusive, 0 elsewhere)
D_2	A dummy variable for 1921–1955, paralleling \bar{S} for phase-average data (= 1 for 1921–1955 inclusive, 0 elsewhere)
D_3	A dummy variable for World War II (= 1 for 1939–1945 inclusive, 0 elsewhere)
D_4	A dummy variable for Competition and Credit Control regulations (= 1 for 1971–1975, 0 elsewhere)
$G(\bar{p} + \bar{i})$	Growth rate of phase-average nominal income (fraction)
H	High-powered money (million £)
I	Real net national product (million 1929 £)
M	Money stock (million £)
N	Population (millions)
P	Deflator of I (1929 = 1.00)
P^*	Deflator of net national product in the United States (1929 = 1.00)
RL	Long-term interest rate (fraction)
RN	$RS \cdot (H/M)$
RS	Short-term interest rate (fraction)
\bar{S}	A dummy variable for phase observations 16–28 (1921–1955; = 1 for observations 16–28 inclusive, 0 elsewhere)
\bar{W}	A dummy variable for phase observations 13–15 and 26–28 (1918–1921 and 1946–1955; = -4, -3, -2, 8, 5, and 3 for phase observations 13, 14, 15, 26, 27, and 28, respectively; 0 elsewhere)

Coefficients and estimated standard errors of the dummies D_1 , D_2 , D_3 , (but not D_4), \bar{S} , and \bar{W} are reported times 100 for readability.

The data are as in Friedman and Schwartz (1982 tables 4.8, 4.9), but relevant series are rescaled proportionately from 1871 to 1920 to remove the break in 1920 when southern Ireland ceased to be part of the United Kingdom. Also, P , P^* , $G(\bar{p} + \bar{i})$, RS, and RL have been divided by 100 so that the values of P and

P^* in 1929 equal 1.00 (rather than 100) and the interest rates and $G(\bar{p} + \bar{i})$ are expressed as fractions (rather than as percentages).

Data Measurement

We record several important caveats about Friedman and Schwartz's data, over'apping those which they carefully document.

- (i) The choice of monetary measure seems too broad to represent transactions demand, yet too narrow for an overall index of "liquidity." M (above) is based on the U.K. monetary measure M_2 (pp. 111-4) and hence excludes interest-bearing liabilities of building societies but includes interest-bearing bank deposits. However, the building society movement has grown rapidly over the last century to become roughly equal in size to the whole commercial banking sector, and building society liabilities are among the most liquid assets available to the personal sector. Note that money-stock figures are centered on mid-years by averaging successive end-of-year values.
- (ii) The measurement of the price series (P) is adjusted for rationing and controls (pp. 115-20), with real income then derived by deflating nominal income. However, it is unreasonable to hold measured nominal income constant when measured prices are believed to be incorrect. Furthermore, over a century, one must be concerned about the effects on the measurement of P of the many dramatic changes that have occurred in quality-adjusted relative prices.
- (iii) Friedman and Schwartz emphasize an "errors-in-variables" paradigm and claim that the importance of errors in variables is reduced by phase-averaging but enhanced by differencing (p. 86). All the variables undoubtedly contain substantial measurement errors, especially when interpreted as correspondences to economically meaningful latent constructs, but time series of over a century will also contain systematic errors. Differencing would remove most effects of such errors, whereas averaging is of little help if errors are persistent (e.g., highly autoregressive).

Resolution of these difficulties is outside the scope of this paper, but they must influence the interpretation of the empirical evidence.

Alternative Approaches to Analyzing Economic Data

By MILTON FRIEDMAN AND ANNA J. SCHWARTZ*

This paper compares two approaches to the analysis of economic data: the exclusively econometric approach recommended by Hendry and Ericsson and the more eclectic approach that we employed in our books Monetary History and Monetary Trends. It concludes that the article by Hendry and Ericsson is mislabeled. Their article is not in any relevant sense an evaluation of our "empirical model of U.K. money demand." Rather, it uses one equation from our book as a peg on which to hang an exposition of sophisticated econometric techniques. Insofar as their empirical findings do bear on ours, they simply confirm some of our principal results and contradict none. (JEL 036, 212)

In response to the "on the one hand" and "on the other hand" economist, Frank H. Knight's favorite remark was, "Yes, indeed, there are two sides to every issue: the right side and the wrong side." David Hendry and Neil Ericsson (1991) (hereafter HE) take the same position—though in their case seriously not jocularly—about how to do empirical research in economics: HE's way and the wrong way. We are more eclectic. We believe that there is no magic formula for wringing reasonable conjectures from refractory and inaccurate evidence. The HE approach is one way: start with a collection of numerical data bearing on the question under study, subject them to sophisticated econometric techniques, place great reliance on tests of significance, and end with a single hypothesis (equation), however complex, supposedly "encompassing"—to use one of HE's favorite terms—all subhypotheses. Another way is to examine a wide variety of evidence, quantitative and nonquantitative, bearing on the question under study; test results from one body of evidence on other bodies, using econometric techniques as one tool in this process, and build up a collection of simple hypotheses that may or may not be readily viewed as components of a broader all-embracing

hypothesis; and, finally, test hypotheses on bodies of data other than those from which they were derived. Both ways—and no doubt still others as well—have their use. None, we believe, can be relied on exclusively.

I. A Comparison of Approaches

The wide difference between HE's approach and ours is clear from HE's section II, in which they "discuss the money-demand relationships they [we] estimated from the phase-average data for the United Kingdom" (HE, p. 9). From the literally hundreds of regressions in *Monetary Trends* (Friedman and Schwartz, 1982), they included four in their table 1 and concentrated their fire on only one of them. They assert that our regression for U.K. money demand is misspecified, "is not an adequate characterization of the data" (HE, p. 15) and does not support any of our "main claims about the United Kingdom" (HE, p. 32). They use that regression as a textbook example to illustrate a collection of sophisticated statistical techniques and to call the reader's attention to the technical statistical literature dealing with those techniques—most of it published after our book went to press.¹ That may be a good way to intro-

*Friedman is Senior Research Fellow, Hoover Institution, Stanford University, and Professor Emeritus of Economics, University of Chicago; Schwartz is Research Associate, National Bureau of Economic Research.

¹Out of 108 total references in HE's list, 70 were published after 1981, the year our book went to press; also, 20 out of 23 articles that were authored by Hendry alone or with collaborators.

duce students to the particular techniques covered and to the associated literature—which, we hasten to add, we are not competent to deploy, let alone judge—but it provides little if any evidence that is relevant to judging the validity of our analysis of money demand.

Hendry and Ericsson are entirely right that the one regression they subject to detailed scrutiny is not *by itself* adequate support for our “main claims about the United Kingdom” (see the Addendum to this article, in which Milton Friedman relates an experience that contributed to his skepticism about relying on a single regression produced by the HE approach). If that regression had been the only source of our “claims,” we would never have made them. As we emphasize in our book—partly in a passage that HE quote but also elsewhere—we do not have much confidence in “what has become the prevailing fashion in econometric work, the immediate computation of multiple regressions including all variables that can reasonably be regarded as relevant” (p. 215). The regression they analyze was selected from a table on page 282 (all unidentified page references herein are to Friedman and Schwartz [1982]) that contains six regressions, three for the United States and three for the United Kingdom, and was itself a prelude to presenting two equations “as a final summary of our results” for the United States and the United Kingdom combined (p. 284).

By HE’s standards, the prior 281 pages of our book are mostly worthless. Indeed, as we shall shortly demonstrate, while they may have skimmed those pages, they have apparently not thought it worthwhile to read them carefully. Those pages were not devoted, à la HE, to “representing the joint density of [a limited set of variables] in terms of an autoregressive-distributed lag model,” then proceeding to simplify “[t]he conditional model...to an ECM [error-correction model],” and to evaluating it “in light of the model design criteria” listed in their table 2 (HE, pp. 22–3). Instead, the first 204 of those 281 pages present our theoretical framework, our statistical framework, the basic data, and an overview of the

movements of money, income, and prices over the century our data cover. We end our broad overview by noting “three phenomena that require further interpretation: first, the common movement of nominal money and nominal income; second, the largely common movement in velocity in the United States and in the United Kingdom; third, the rather different relations in the two countries between movements in money, on the one hand, and real income and prices on the other” (pp. 184–5). Only then, in Chapter 6, “Velocity and the Demand for Money,” do we explore the first of the three phenomena, and, in subsequent chapters, the other two phenomena.

Throughout, our aim is to explain movements longer than a business cycle and to abstract from strictly intracyclical effects. That aim is both less and more ambitious than HE’s. It is less ambitious in that we limit attention to secular effects, while they seek a single econometric specification that simultaneously describes cyclical and secular movements. It is more ambitious in that we use as wide a range of evidence as we can, including qualitative examination of historical experience as well as numerical data for more than a century for both the United States and the United Kingdom. A major purpose of our book was to “give numerical content to some of the elements and hypotheses embedded in” “the broad theoretical framework that guided our earlier study of United States monetary history” “as well as some of the generalizations suggested by *A Monetary History*” (p. 13 *passim*). Accordingly, we frequently draw on evidence for the United States presented in the earlier book (Friedman and Schwartz, 1963). In particular, we use independent data for the United Kingdom to test generalizations initially suggested by U.S. experience.

The difference between HE’s approach and ours is exemplified by one of the test “criteria” by which they judge our equation unacceptable, namely that “[t]he values of $\hat{\sigma}$ [the standard error of estimate] for the corresponding subperiods [the first and second half, 1875–1928 and 1928–1975] are markedly different: 2.8 percent and 6.0 per-

cent, respectively" (HE, p. 13). On page 175 of our book, we noted that "For the United Kingdom, for the period before 1914, the extensive use of interpolation . . . biases sharply downward both the initial and the residual variation." In consequence, if the error of estimate had been the same in the two periods HE compare, we would have regarded that fact as evidence *against*, not for, our equation. That would have meant that we had erroneously attributed pure measurement error to economic variables. Similarly, the finding by HE that the equations they prefer (their equations 10 and 11) have the same residual variability before and after 1914 (not 1928) is, in our view, evidence against, not for, their equations.

They say, we "do not formally test for constancy" (HE, p. 13) by which they mean we do not use the particular statistical tests that they advocate; but we certainly do test for constancy by comparing regressions for different periods, trying to isolate features of the statistical data that may bias comparisons, drawing on historical data, and in a variety of other ways. We regard such tests as far more reliable and, to use a statistical term, robust than the formal statistical tests used by HE.

Another example is their assertion that "price homogeneity" incorporated in our model is rejected by their statistical test and their accompanying comment that, when we "tested for trends and price homogeneity in more restrictive models, they [we] did not obtain rejections" (HE, p. 15). From our viewpoint, the tests for price *and* population homogeneity on pages 253-9 were less, not more, restrictive than HE's test.² Our tests were for both the United States and the United Kingdom, used both levels and rates of change, and allowed for the "regression effect," of which more later, as well as for a variety of possible explanatory variables. We concluded that the results were "reasonably consistent with the" assumption that "any change in prices or population implied an equal percentage change in the quantity of

money demanded (mathematically, the demand for money in nominal terms is homogeneous of the first degree in population and prices)" (pp. 258, 253). We hasten to add that our conclusion was for a long-run demand function, not for a function seeking to cover intracyclical effects.

Still another example is HE's rejection of our use of phase averages and their decision to analyze our "original annual observations" (HE, p. 18). That is a correct decision for their objective: a single equation that "encompasses" both secular and cyclical effects. However, that was not our objective. We devoted pages 79-97 to testing whether the phase averages and rates of change contain a residual cyclical element and whether they are infected by a spurious serial correlation. We concluded "that our phase bases do eliminate the bulk of the systematic cyclical fluctuation" and "that the 'noise' introduced by the serial correlations is sufficiently small relative to the systematic variation we are trying to describe that it can for the most part be neglected" (pp. 81, 97). True enough, we discovered, as HE do, that annual observations give essentially the same results as phase-average data for the regression they analyze, and its counterpart for the United States (see Friedman, 1988 footnote 16). However, we doubt that we would have settled on those specific final equations if we had relied solely on annual data in our prior exploratory investigation. Throughout that investigation, we did not have to allow for cyclical effects, or explore a "(dynamic) error-correction representation of the relevant variables" (HE, p. 20), as we would have had to do if we had followed HE's prescription. Hence, we remain unpersuaded that our use of phase-average data was a mistake.

II. Exogeneity

Hendry and Ericsson put much emphasis on "concepts of exogeneity," listing four distinct concepts, and stating: "In no case is it legitimate to 'make variables exogenous' simply by not modeling them" (HE, p. 21). We do not sympathize with such commandments. In our view, exogeneity is not an

²So far as we can see, HE nowhere even try to test for population homogeneity.

invariant statistical characteristic of variables. Everything depends on the purpose. In economic analysis, it may be appropriate to regard a variable as exogenous for some purposes and as endogenous for others. A simple example is the quantity of money. For the United States after World War I, we believe it is appropriate to regard the money stock as exogenous (i.e., determined by the monetary authorities) in an economic analysis of long-run money demand. We do not believe it would be equally appropriate to do so for week-to-week or month-to-month movements for which, in HE's words, "the money stock appears to be endogenously determined by the decisions of the private sector" (HE, p. 27). For the period before World War I, as we repeatedly state in both *Monetary History* and *Monetary Trends*, it is not appropriate to regard the money stock as exogenous even for money-demand analysis, particularly for phase averages. For that period, the money stock is best regarded as endogenous, because the United States and much of the rest of the world was on a gold standard. Even for the post-World War I period, it would not be appropriate to regard the money stock as exogenous in a broader study of the Federal Reserve as a political institution, created by Congress, subject to its ultimate control, with members of its Board appointed by the President. For such studies, of which there are a good number, the money stock is best regarded as endogenous.

After their own examination of "exogeneity" and "super exogeneity" for one of their regressions, HE assert that "This evidence is inconsistent with the hypothesis that, over the period 1878–1970, exogenous money determined prices in the United Kingdom via a stable demand function, *precisely because we have established a constant money-demand model conditional on prices*" (HE, p. 30). We interpret their italics as implying that we asserted the hypothesis that they regard as contradicted. We clearly did nothing of the kind. In particular, a large part of our next chapter (Ch. 7) explores the direction of influence of the variables HE consider as well as the direction of influence between the United States and the United

Kingdom. We distinguish different monetary regimes and examine separately the gold-standard period and the variable-exchange-rate period. At the outset of Chapter 7, we note that "one possible explanation for the similar behavior of [velocity] is that the two countries were part of a single economic entity" (p. 305). We go on to note that before World War I, when both countries were on a gold or sterling standard, "as we demonstrated in *A Monetary History*, ... there was a good deal of leeway for domestic monetary policy over short periods, but over periods of more than a few years, the quantity of money in each country was determined by the requirement that the price levels of the two countries move roughly in step in order to preserve equilibrium in the balance of payments" (p. 306). Clearly, we are not guilty of the sin that we suspect, perhaps wrongly, HE accuse us of.

III. The Regression Effect

On the purely statistical level, we tried throughout to avoid making arbitrary assumptions about exogeneity. For example, in the first table in Chapter 6 (table 6.1, p. 212), we label one set of equations "Level of Money: Income Assumed Exogenous" and another "Level of Income: Money Assumed Exogenous" and do the same for rate-of-change calculations. Similar caution in later tables derives in large part from our trying systematically to allow for what we referred to earlier as "the regression effect."

The regression effect refers to the bias introduced by stochastic disturbances ("error") affecting a variable treated as exogenous. Indeed, regression analysis got its name from this bias.³ Put formally, consider a relation between two variables (x and y) that is strictly linear. Given errors of mea-

³In studying the relation between the heights of fathers and sons, Sir Francis Galton discovered that the average height of sons of tall (short) fathers "regressed" to the mean (i.e., differed from the average height of all sons by less than their fathers' height differed from the average height of all fathers) and, simultaneously, the average height of the fathers of tall (short) sons also "regressed to the mean."

surement, a sample of observed values of the two variables will yield a bivariate scatter, rather than a strictly linear relation. The calculated regression of y on x will be flatter than the "true" relation, and that of x on y will be steeper. Harold Hotelling pointed out in 1933 how potent a source of economic fallacies the regression effect can be if "errors of measurement" are interpreted to include all stochastic disturbances affecting the variables under study (Hotelling, 1933, 1934; Horace Secrist, 1934; Friedman and Simon Kuznets, 1945 pp. 325–38; Friedman, 1957 Ch. 3).

A major difference between our statistical approach and HE's is that we allow systematically for the regression effect. HE obliquely recognize this difference in their data appendix, where they note near the end that we "emphasize an 'errors-in-variables' paradigm" (HE, p. 34). Nowhere else do they mention or refer to the regression effect or seek to allow for it. In our opinion, it is often a more important source of error—because it introduces systematic bias—than is the residual error described by the standard error of estimate to which HE give exclusive attention.

In our analysis, as in many economic analyses, the so-called "independent" or "exogenous" or "predetermined" variables are infected by error in a double sense. In the first place, they are not always precise empirical counterparts to the economic variables that theory suggests including. To illustrate, we regard the yield on physical assets as one of the interest rates that can be expected to affect the real quantity of money demanded. However, despite considerable exploration, we could not find a direct empirical counterpart. We finally settled on using the rate of change of nominal income as a "proxy for the nominal return on physical assets" (pp. 274–80). As a second example, we consider as another relevant variable, the own yield on money, to which HE refer in the final paragraph of their section IV, citing a 1987 article, but do not empirically explore. Here again, we were unable to find a reliable reasonably direct measure, though further statistical exploration of basic data may enable such a mea-

sure to be constructed. Instead, we use an indirect measure suggested by Benjamin Klein (1970) and described by HE in their footnote 26. (We examine the whole issue on pp. 259–73.) In both cases, even if the proxy were measured precisely, there would remain measurement error equal to the difference between the relevant economic variable and the proxy used as its empirical counterpart.

In the second place, the proxy variable is never measured precisely, so there is a measurement error in the ordinary sense that adds to the total measurement error. When these measured variables are used in a regression as independent variables, their coefficients are biased estimates of the underlying theoretical coefficients. One way to estimate the possible size of the bias is to reverse the direction of regression: in the bivariate case, to estimate both a y -on- x regression and an x -on- y regression. The resulting estimates of the theoretical coefficients provide an upper and a lower limit. A similar procedure can be used to get upper and lower limits in multiple regressions. We discussed this issue at some length and dealt with it by consistently calculating such limits for essentially all of the parameters we estimated.⁴ In principle, the limits should be made still wider to allow for the usual standard error of estimate of the parameters arising from the stochastic element in the dependent variable. We did not do so; however, we consistently presented t ratios, from which what is generally called the "sampling error" can be readily calculated, so that any interested reader can combine the two.

An example shows the importance of the regression effect compared with the conventional "sampling error" that is HE's sole concern. Consider the coefficient of the interest rate that HE refer to in their section

⁴See especially Chapter 5, footnotes 28 and 29, pp. 173–4; Chapter 6, footnote 7, p. 211, footnote b to table 6.1, p. 213, footnote 18, pp. 224–5; and the text to which these footnotes are attached, as well as comments scattered throughout the text in discussing particular sets of results.

II and plot in their figure 5. Our upper and lower point estimates allowing for the regression effect differ by 28.6 (table 6.15, p. 285). One estimate of the standard error of the coefficient is 3.26.⁵ Even four times the standard error (plus or minus twice the standard error) is 13.04, or less than half the regression effect. Combining the sampling error and the regression effect gives a range for the coefficient from -4.6 to -46.3 , the basis for our statement that this coefficient was "much less precisely estimated" than the income elasticity, for which the regression effect was 0.08, the standard error of estimate of the parameter 0.005, so the combined range was 0.87–0.97.

This example is, we believe, fairly representative with respect to the relative importance of the regression effect and the regularly computed standard error of estimate of parameters. It suggests why we attribute so much importance to the regression effect, or alternatively, why we regard the "errors-in-variable model" as appropriate for economic data that are subject to large differences between the theoretical variables and their statistical counterparts and to large measurement errors.⁶

IV. The Proof of the Pudding

Hendry and Ericsson's final products which, by comparison with our results, they describe as a "better-fitting, constant, dynamic, error-correction (cointegration) model" (HE, p. 8) and which satisfy all of

their statistical "criteria for evaluating and designing models" (HE, p. 19) are their regressions 10 and 11, the first, with 10 parameters, omitting the five final years, 1971–1975; the second, with 12 parameters, covering the whole period, 1878–1975. These are in turn simplifications of the "general autoregressive-distributed lag" regression in their table 3 containing 37 parameters and omitting the final five years. How do their results compare with ours? In terms of the long-run effects we were interested in, they simply confirm a few of our results.

A. Income Elasticity of Money Demand

Our point estimate of the elasticity of per capita real demand is 0.88; allowing for sampling error by adding plus or minus twice the standard error of estimate of the relevant parameter gives a range of 0.87–0.89; allowing also for the regression effect gives, as noted earlier, a range of 0.87–0.97. The regression yielding these estimates has six parameters.

Neither HE's regression 10 nor their regression 11 contains an explicit income term. The reason is presumably their prior conclusion, embodied in regression 9 and apparently regarded by them as confirmed by the 37-parameter regression in their table 3, that the income elasticity of aggregate money demand is unity. Nowhere do they allow for population (unless implicitly in the constant terms of regressions 10 and 11). Since we decided that the elasticity of money demand with respect to population could be taken as unity, the aggregate elasticity can be expected to be closer to unity than the per capita elasticity. The regression in HE's table 3 does include income separately and so permits an elasticity other than one. If we convert it into a long-run regression by adding the coefficients of the separate lag terms, as is done in the final column of the table, the result is an eight-parameter regression and a point estimate of the income elasticity of 1.1. Clearly there is no contradiction between their estimate and ours if allowance is made for both sampling error and the regression effect.

⁵"One estimate" because it is from one of the two regressions from which we calculate the limits (e.g., y on x). The other regression (e.g., x on y) would give a somewhat different estimate.

⁶In re measurement error, in a later chapter (Ch. 8), we use a highly indirect approach to estimate the pure measurement error in our data. For the phase-average level of nominal income, we estimate that the standard deviation of pure measurement error is 2.5 percent for the United States, 4.5 percent for the United Kingdom. For the rate of change of nominal income computed from the phase averages, we estimate the corresponding standard deviations to be 0.74 of a percentage point for the United States and 0.58 of a percentage point for the United Kingdom (pp. 350–1). These are appreciable, yet not unreasonable.

B. Interest Semielasticity of Money Demand

Our point estimate of the semielasticity of money demand with respect to the differential yield on money (the short-term interest rate minus our proxy for the own-rate on money) is -11.16 . This implies that a *one percentage point* increase in the differential interest rate reduces the real quantity of money demanded per capita by 11.16 percent. As noted earlier, we regard this estimate as not very well determined and the range, including both sampling and regression effects, is extremely wide, from -4.6 to -46.3 , though, as theory would lead one to expect, negative throughout.

HE produce no strictly comparable elasticity. They use the short-term interest rate but do not allow for the own rate.⁷ In commenting on their equation 9, they state that it "implies that a one-percentage-point increase in the short-term interest rate... reduces [velocity]... by 7 percent in the long run," (p. 25) or that their estimate of the semielasticity of the short-term interest rate is -7 , well within our estimated range.⁸

C. Postwar Readjustment and Demand Shift

Our regression includes two dummy variables to allow for postwar readjustment and a demand shift. HE remark that "many investigators would regard the need for the data-based shift dummy \bar{S} spanning one-

third of the sample as *prima facie* evidence against the model's constancy" (HE, p. 13). However, the regression in their table 3 has three dummy variables, one of which is the precise counterpart of our demand shift dummy \bar{S} ; the other two, like our postwar adjustment dummy, allow for wartime effects. Their regression 10 combines the two wartime dummies but does not explicitly use a demand-shift dummy. Their regression 11 introduces an additional dummy for the 1971-1975 period.

The coefficient of our demand-shift dummy is 0.21, implying that the demand for money shifted upward by 21 percent during the period in question. Adding and subtracting two standard errors of estimate gives a range of 0.15-0.27. HE's table 3 gives a point estimate, in units comparable to our estimate, of 0.06 but with a very large standard error, so that adding and subtracting two standard errors gives a range from -0.29 to $+0.41$. Commenting on their "simplified" regression 10, HE note that it "exhibits multiple equilibria, with two corresponding to the long-run solution (9) and a third being that solution shifted by 20 percent. In that sense, the results are consistent with the use of an adjustment factor of about that order [i.e., 21 percent] by Friedman and Schwartz" (HE, p. 26). We have not been able to devise any ready way to compare our estimate of the postwar readjustment effect with the effect of their two wartime dummies.

D. Differences in Scope

So far, the HE results simply confirm ours. In addition, we 1) estimated the effect of the proxy yield on physical assets, a variable they do not consider; 2) allowed for the effect of the own-yield on money, which they postpone for future work; 3) compared demand functions in the United States and the United Kingdom, concluding that the only important difference was a higher income elasticity for the United States than for the United Kingdom; and 4) estimated two regressions for the two countries combined, including one additional dummy to allow for the difference in income elasticity.

⁷However, in their footnote 26, HE assert that they experimented with using our proxy and that "The resulting estimates are very similar to those found using" only the short-term rate.

⁸In one of our preliminary regressions that HE do not refer to, the point estimate of the semielasticity for the short-term rate alone is -3.0 ; the range, allowing for both sampling error and the regression effect, is from -1.4 to -11.1 , again including their -7 (see tables 6.12 and 6.N.3, pp. 272-3 and 277).

The long-run regression derived from HE's table 3 contains both a short-term and a long-term interest rate. However, as judged from the final column, the coefficient of neither comes close to being significantly different statistically from 0, and any range constructed from those point estimates is so wide as to be meaningless.

ties. HE, as part of their more ambitious agenda, estimate the short-run error-correction process, something that we explicitly excluded from our study.

E. Encompassing

Hendry and Ericsson put a great deal of emphasis on whether one "model" encompasses another. They assert that "a necessary condition for encompassing is *variance dominance*, where one equation variance-dominates another if the former has a smaller error variance" (HE, p. 22). A footnote attached to this sentence states: "Formally, variance dominance refers to the underlying (and unknown) error variances. Without loss of clarity, we often will say a model variance-dominates another if the *estimated residual* variance of the former is smaller than of the latter." In other words, they judge the validity of their hypotheses by the data from which they derive them!

In this spirit, they boast that "the error variance of (10) is less than one-tenth of that in" our regression (HE, p. 27); but this is to compare apples and oranges. Their regression 10 has a first difference or a rate of change as a dependent variable. The regression they compare it with has the logarithm of the level of money as the dependent variable. They present only two regressions in log levels: their regression 9 and the regression in their table 3. The standard error of estimate for regression 9 is nearly twice the standard error of estimate of our regression; for the regression in their table 3, it is nearly three times higher.⁹

We also estimated a parallel regression in rates of change, comparable to HE's regressions 10 and 11. It has six parameters and a standard error of estimate of 1.34, compared with 1.424 for their 10-parameter regression 10, which covers a shorter period than ours, and 1.478 for their 12-parameter

regression 11, which covers the same period as ours. In their terms, our regression variance-dominates theirs. They obliquely recognize the problem and try to justify their procedure: "Although (10) has a rate of change as the dependent variable, it is an equation in log-levels because of the error-correction term..., so direct comparison [with our log-level equation] is valid" (HE, p. 27). However, their "error-correction terms" are useful primarily for short-run analysis of levels, not for the long-run effects that were our sole concern.

HE's regressions 10 and 11 are misleading for a very different reason as well. The same variable, Δp_t , is included on both sides of the equation: as part of the dependent variable and also as an independent variable. Adding Δp_t to both sides of the regression does not change its statistical characteristics ($\hat{\sigma}$, the standard errors of the parameters, and the coefficients of all terms other than Δp_t are unchanged). What it does make clear is that the regression "explains" a change in the nominal quantity of money, not the real quantity of money (is it, perhaps, best interpreted as an estimate of a short-run supply curve of nominal money?).

We have been unable to duplicate regression 10 precisely, but we have come reasonably close. Omitting Δp_t from the right-hand side nearly doubles the standard error of estimate (2.83 percent versus 1.50 percent).¹⁰ A parallel equation with Δm_t as the independent variable, and omitting Δp_t , gives a standard error of estimate one-third larger than that from our estimate of regression 10 (2.07 percent versus 1.50 percent). That is a reasonably satisfactory empirical equation for the change in the nominal quantity of money. However, we are hard put to construct any satisfactory theoretical interpretation of the regression.

HE refer favorably to papers by Andrew Longbottom and Sean Holly (1985a) and by Alvaro Escribano (1985), which they regard

⁹The standard error of estimate for our regression is 5.54 percent; for HE's regression 9, it is 10.86 percent; for that in their table 3, it is 15.5 percent (it is given as 1.55, but that has to be multiplied by 10 to be comparable to the other two, since the long-run dependent variable is $0.1m$).

¹⁰HE report the standard error of estimate as 1.424 percent. Our attempted duplicate has a standard error of estimate of 1.50 percent.

as producing "significant improvements on our [i.e., HE's] 1983 model" (HE, p. 24) but still leaving room for further improvement, as in HE's revised models. In a slightly later paper by Longbottom and Holly (1985b), which HE do not refer to but which, like the earlier paper, uses HE's proposed procedures, the final summary is: "In this paper we have re-examined Friedman and Schwartz's work on UK monetary trends in the light of the methodological criticisms of Hendry and Ericsson. In contrast to Hendry and Ericsson we are able to find empirical support for the claims that Friedman and Schwartz make about the form and long run stability of the demand for money function in the UK since 1878" (Longbottom and Holly, 1985b p. 19).

We hasten to add that we regard the Longbottom and Holly papers no less an example of formal econometric analysis carried to extremes than HE's papers. Their confirmation of our results does not increase our confidence in our results any more than HE's assertion that we have failed "to present statistical evidence pertinent to their [our] main claims about the United Kingdom" (p. 32) weakens our confidence in them. Our confidence in our results derives, as we have stressed repeatedly, from a much broader base and would not be justified if their analysis was all we had to rely on.

F. *The Real Proof of the Pudding*

Before ending this section, in which we have expressed so much skepticism about HE's approach, we should indicate what evidence would persuade us that we are wrong and they are right. The answer is straightforward. A persuasive test of their results must be based on data not used in the derivation of their equations. That might mean using their equations to predict the same kind of phenomena for other countries, or for a future or earlier period for the United Kingdom, or deriving testable implications from their equations for other variables, such as exchange rates, term structure of interest rates, or still other phenomena we are not imaginative enough to list. Similarly, that is the only kind of evi-

dence that we would regard as persuasive with respect to the validity of our own results.¹¹

V. Conclusion

Hendry and Ericsson describe their paper as an evaluation of "an empirical model of U.K. money demand developed by Friedman and Schwartz in *Monetary Trends*" (HE, p. 8). Viewed from that point of view, seldom can a mountain have labored so hard and produced so small a mouse. After years of experiments, HE's econometric techniques produced a series of models that confirm some of our principal results, contradict none, and are less successful than our equations in terms of their own criterion of variance-dominance.

But their paper is mislabeled. It is not in any relevant sense an evaluation of our "empirical model of U.K. money demand." They use one out of our hundreds of regressions as a peg on which to hang an exposition of a set of sophisticated econometric techniques designed for a purpose and embodying a methodological approach very different from ours. Their regressions are designed to explain the short-term adjustment process as well as the long-term relation. We had no such ambitious aim.

We are incompetent to judge the adequacy of their techniques for estimating the short-term adjustment process. However, we do not regard their statistical tests as demonstrating the validity of their statistical estimates. Their estimates are the end result of trying a large number of alternative hypotheses on a single body of data. As a result, it is impossible to specify how many

¹¹Our initial draft of *Monetary Trends* was based on U.S. data only. We expanded it to include the United Kingdom precisely in order to test our initial generalizations with data other than those used in deriving them. This is of course a never-ending process; the generalizations in the published book in their turn should be tested against data not used in deriving them. One minor such test extending the period originally covered is that in Friedman (1988 footnote 16). A regression for the United States for 1886-1985 using annual data gives essentially the same results as our phase-average equation for 1873-1975.

"degrees of freedom" have been used up in the process of reaching the final equations presented, or, put differently, to estimate the probabilities that their results could have arisen from chance. For that, one needs, in their words, "the underlying (and unknown) error variances," not "the *estimated residual variance*" on which they rely (HE, footnote 14). As already indicated, the real proof of their pudding is whether it produces a satisfactory explanation of data not used in baking it—data for subsequent or earlier years, for other countries, or for other variables. One example of such a test, in a physical-science context, is given in the Appendix. That example dramatically illustrates how misleading a multiple regression can be for predictive purposes, even though it satisfies all the standard tests.

APPENDIX: A CAUTIONARY TALE ABOUT MULTIPLE REGRESSIONS

*(This addendum was written by
Milton Friedman)*

My skepticism about relying on a single multiple regression that results from the HE approach traces back to an experience I had in 1944 or 1945 when I was engaged in war research as a member of the staff of the Statistical Research Group of Columbia University.

One of my assignments was to serve as a statistical consultant to a number of projects seeking to develop an improved alloy for use in airplane turbo-superchargers and as a lining for jet engines. The goal was to develop alloys that could withstand the highest possible temperature, since the efficiency of a turbine (or its equivalent) rises very rapidly with the temperature at which it can safely operate. I served as something of a clearing agency for the results of the various experiments in progress, as an adviser on statistical design of experiments, and as an analyst of the results, producing a fairly regular newsletter on these matters for the experimenters.

The procedure in testing an experimental alloy was to hang a specified weight on a standard turbine blade made from the alloy,

put it in a furnace capable of generating a very high temperature, and measure the time it took for the blade to break. At one point, I combined the test data from all the separate experiments and engaged in precisely the kind of analysis that HE recommended. I ended up with a single proposed regression that expressed time to fracture as a function of stress, temperature, and variables describing the composition of the alloy. I assured myself that the equation was consistent with metallurgical theory.

The major problem then, trivial now, was to compute the parameters of the equation and the associated test statistics. That was the age of the desk electric—not electronic—calculators and the Dolittle method of computing regressions. The labor involved in that method increases exponentially with the number of independent variables. For the number I wanted to use, we estimated that it would take three months for one of our highly skilled operators to calculate the equation. Fortunately, we discovered that there was one large-scale computer in the country that could perform our calculations: the experimental Mark I (or something like that) at Harvard, itself not electronic but built from a large number of IBM card-sorting machines housed in an enormous air-conditioned gymnasium. We were granted time on the machine to perform our calculations. Today's statisticians will be interested to know that, not counting data insertion, it took 40 hours to calculate a regression that I can now calculate on my desktop computer in less than 30 seconds—my favorite story to illustrate what has happened to our computer power.

I was delighted with the calculated regression. It had a high multiple correlation, low standard error of estimate, and high t values for all of the coefficients, and it satisfied every other test statistic that I knew of more than 40 years ago. I immediately set to work to create some new and better alloys. In constructing such alloys, I had to go outside the joint range of my sample set of independent variables, but I was careful to stay as close as I could and to be within the limits used in prior experiments for each variable separately. The technical details are

irrelevant for the present purpose, and I could no longer reproduce them in any event.

The bottom line is that I ended up constructing two new alloys (which with hope combined with caution, I named F-1 and F-2). According to the calculated regression, each would take several hundred hours to rupture at the very high temperature I proposed to test them at, a sizable multiple of the best recorded time for any previous alloy. This was physics, not economics, so I did not have to wait years to see whether the predictions from my equation were correct. I phoned an MIT lab that was working on alloys of a similar type and asked them to cook up and test my two alloys. I was sufficiently skeptical—or perhaps just cautious—so that I was careful not to tell them what to expect. A few days later they phoned the results: my two alloys had ruptured in something like 1–4 hours, a much poorer outcome than for many prior alloys. F-1 and F-2 were never heard of again.

Ever since, I have been extremely skeptical of relying on projections from a multiple regression, however well it performs on the body of data from which it is derived; and the more complex the regression, the more skeptical I am. In the course of decades, that skepticism has been justified time and again. In my view, regression analysis is a good tool for deriving hypotheses. But any hypothesis must be tested with data or non-quantitative evidence other than that used in deriving the regression or available when the regression was derived. Low standard errors of estimate, high t values, and the like are often tributes to the ingenuity and tenacity of the statistician rather than reliable evidence of the ability of the regression to predict data not used in constructing it.

The Failure of Competition in the Credit Card Market

By LAWRENCE M. AUSUBEL*

The bank credit card market, containing 4,000 firms and lacking regulatory barriers, casually appears to be a hospitable environment for the model of perfect competition. Nevertheless, this article reports that credit card interest rates have been exceptionally sticky relative to the cost of funds. Moreover, major credit card issuers have persistently earned from three to five times the ordinary rate of return in banking during the period 1983–1988. The failure of the competitive model appears to be partly attributable to consumers making credit card choices without taking account of the very high probability that they will pay interest on their outstanding balances. (JEL 315, 612).

This article presents and discusses a collection of data which is paradoxical within the paradigm of perfect competition. The market studied, the bank credit card industry in the United States, contains literally 4,000 firms who sell a relatively homogeneous good to 75 million consumers. The ten largest firms account for only about two-fifths of market share. Firms have historically operated without regulatory barriers to conducting business across state lines—and at least 20 firms aggressively solicit business on a national scale. Firms have also operated in the virtual absence of price regulations for most of a decade. There do not appear to be any particularly con-

strained inputs, significant sunk costs, or significant barriers to entry. Finally, there is no evidence of any explicit collusion on price or quantity.

Given such a favorable market description, or one not even half so optimistic, many economists would prefer to presume that the market must behave as a competitive spot market in continuous equilibrium. It is the purpose of this article to argue that this presumption is empirically unjustified in the market for bank credit cards in the 1980's. Section I outlines the market structure of the bank credit card industry. Section II offers empirical evidence of extreme price stickiness in credit card interest rates. Section III provides direct profit data on the industry, arguing that the 50 largest credit card issuers have earned from three to five times the ordinary rate of return for the banking industry during the period 1983–1988. Section IV examines profits over a larger sample of banks and a longer time period. Section V presents additional data on resales of credit card portfolios between banks, suggesting that the extraordinary profits exist *ex ante* as well as *ex post* (and that bankers expect the profitability to persist). Section VI explores some theoretical explanations for price stickiness and supra-normal profits. Section VII calculates what would be "competitive" interest rates. Section VIII briefly discusses the extent of welfare loss in the market and the merits of regulation to correct market failure. Conclusions are presented in Section IX.

I. The Bank Credit Card Market: Is 4,000 Enough for Competition?

Credit cards are the currency of late 20th-century America. The aggregate charge volume on plastic in the United States was estimated at \$375 billion in 1987.¹ Almost half of this total—\$165 billion in volume—was charged on MasterCard and Visa credit cards (the primary focus of this article), and volume was growing at well over 10 percent per year.² The remaining volume arose largely from similar credit cards (e.g., the Discover and Optima cards), “travel and entertainment” cards (e.g., the American Express card), and retail cards (e.g., department store and oil company cards).

Borrowing via credit cards (and all consumer borrowing) is also significant and has been even more of a growth industry. Outstanding U.S. balances on revolving credit accounts equaled \$203 billion at year-end 1989, up from only \$70 billion in 1982.³ More than \$130 billion of this total consisted of MasterCard and Visa balances, more than a threefold increase from 1982, and bank card balances were still increasing at more than a 15-percent annual rate.⁴ Overall outstanding consumer installment credit balances in the United States reached \$717 billion, up from \$356 billion in 1982;⁵ it is worth observing that many of the considerations explicitly discussed here in con-

nection with the credit card industry apply also to other forms of consumer borrowing (especially other unsecured credit).

If Visa and MasterCard were the relevant levels of business to examine, then two firms would control a substantial part of the credit card market. However, most relevant business decisions are made at the level of the issuing bank. Individual banks own their cardholders' accounts and determine the interest rate, annual fee, grace period, credit limit, and other terms of the accounts. (Only charges such as the “interchange fee” from the merchant's bank to the cardholder's bank are standardized, and the cardholder's bank appears only to break even on such charges. Moreover, there is absolutely no indication that the MasterCard and Visa organizations serve to facilitate collusion on other prices.⁶) In essence, MasterCard International and Visa U.S.A. are organizations largely irrelevant to this discussion; “firms” will henceforth refer to the issuing banks.

The market for MasterCard and Visa cards, thus, is relatively unconcentrated. The top ten firms control only about two-fifths of the market, and the next ten firms control only one-tenth of the market (see Table 1). Moreover, the market is exceptionally broad. A bank that ranked number 100 in 1987 still had approximately 160,000 active accounts, \$125 million in outstanding balances, and \$250 million in annual charge volume.⁷

Unlike most aspects of American banking, the credit card business has historically operated free of interstate banking and

¹Moreover, Americans were estimated to have made 9.1 billion credit card transactions in 1987 (*The Nilson Report*, Number 428, May 1988, p. 5).

²U.S. volume in 1987 consisted of \$138 billion in sales slips (i.e., charged goods and services) and \$27 billion in cash advances. Visa accounted for 59 percent of this value and MasterCard accounted for the remaining 41 percent. (*The Nilson Report*, Number 422, February 1988, p. 6, and Number 423, March 1988, pp. 4–5).

³Federal Reserve Board's series of Consumer Installment Credit, as published in *Federal Reserve Bulletin*, April 1990, table 1.55, line 15 (and previous issues).

⁴*Federal Reserve Bulletin*, April 1990, table 1.55, lines 16, 19, and 21. Revolving credit held by commercial banks, savings institutions, and pools of securitized assets consists almost entirely of MasterCard and Visa balances.

⁵*Federal Reserve Bulletin*, April 1990, table 1.55, line 1 (and previous issues).

⁶Moreover, the observed interest rate behavior does not seem to fit the conventional view of collusive pricing. Around 1985, three major issuers (Chase Manhattan, Manufacturers Hanover, and Maryland Bank) reduced their interest rates on standard cards to the 17.5–17.9-percent range. Far from this triggering an industry price war, other major issuers (e.g., Citibank and First Chicago) steadfastly maintained 19.8-percent rates on most accounts, without apparent detriment to their customer bases. Finally, in the spring of 1989, the three price-cutters announced rate increases, apparently finding *without facing retaliation* that the earlier cuts had been unprofitable (*The New York Times*, April 27, 1989, p. 32; *Wall Street Journal*, March 22, 1989, p. B1).

⁷*The Nilson Report*, Number 406 (June 1987), p. 7.

TABLE 1—TOP TEN ISSUERS OF MASTERCARD AND VISA CARDS, 1987

Bank	Number of accounts	Percentage market share (by number of accounts)	Outstanding balances (\$ billion)	Percentage market share (by outstanding balances)
Citibank	10,000,000	8.4	\$15.3B	16.3
Chase Manhattan Bank	5,000,000	4.2	\$5.4B	5.8
Bank of America	4,800,000	4.0	\$5.2B	5.5
First Chicago	4,500,000	3.8	\$4.6B	4.9
Manufacturers Hanover	3,300,000	2.8	\$2.0B	2.1
Wells Fargo Bank	1,800,000	1.5	\$2.8B	3.0
Maryland Bank	1,800,000	1.5	\$1.7B	1.8
Marine Midland Bank	1,700,000	1.4	\$1.4B	1.5
Chemical Bank	1,500,000	1.3	\$1.3B	1.4
Associates National Bank	1,200,000	1.0	\$1.0B	1.1
Top ten	35,600,000	30.0	\$40.7B	43.4
Second ten	11,500,000	9.7	\$9.0B	9.6
Total	118,900,000	100.0	\$93.9B	100.0

Sources: Individual banks' numbers of accounts surveyed by *American Banker*, (March 1, 1988, pp. 1–2) and *Credit Card News* (August 15, 1988, pp. 4–16); total number of accounts from *Nilson Report* (Number 406 [June 1987], p. 4). Individual banks' outstanding balances based on *American Banker* (September 21, 1987, p. 43 [call report data]) and *Nilson Report* (Number 406 [June 1987], pp. 4–5); total outstanding balances from *Federal Reserve Bulletin* (December 1988, table 1.55; revolving credit outstanding at commercial banks and savings institutions, minus loans outstanding at Greenwood Trust Co. [Discover card] and American Express Centurion Bank). Data reported for December 31, 1986, adjusted for acquisitions effective in 1987. Conflicts between sources were resolved using best available information.

branch banking restrictions. Indeed, the largest issuers today conduct truly national businesses. For example, Maryland Bank (ranked number seven in Table 1) conducts business in all 50 states and has only five percent of its accounts in its home state.⁸ The only states where more than five percent of its business is concentrated are California (10.7 percent), Texas (6.7 percent), Pennsylvania (6.0 percent), and New Jersey (5.8 percent).

In the past, credit card issuers were constrained by state usury laws. However, the U.S. Supreme Court's December 1978 *Marquette* decision paved the way for the practical elimination of price regulations.⁹ The

Court held that only the usury ceiling of the state in which the bank is located, and not that of the state in which the consumer is located, restricts the interest rate the bank may charge. This gave banks the option of shifting their credit card operations to wholly owned subsidiaries situated in states without usury laws. By 1982, amid *Marquette*-created bank pressure and historically high market interest rates, most leading banking states had relaxed or repealed their interest rate ceilings. Meanwhile, South Dakota and Delaware had established themselves as attractive homes-away-from-home for credit card issuers. While a number of states maintain binding usury laws at this writing (most notably, Arkansas, with a ceiling of five percentage points above the Federal Reserve discount rate), essentially all major issuers can pursue business in those states free of restric-

⁸"Prospectus for Maryland Bank, N.A., Credit Card Trust 1987-A," December 9, 1987, pp. 17–18.

⁹*Marquette National Bank v. First of Omaha Service Corporation*, 439 U.S. 299 (1978). The *Marquette* decision applies to credit cards issued by nationally chartered banks, but not to retail cards (e.g., oil company credit cards). The decision explicitly permits banks to "export" their interest rates; banks have interpreted this also to permit the "export" of annual fees and

other customer fees. At this writing, at the behest of the Iowa Attorney General, courts are considering whether this rule does indeed apply to fees.

tion. It is fair to say that the bank credit card market in the United States was functionally deregulated in 1982.

II. Credit Card Interest Rate Behavior

A. Sticky Interest Rates

The cost of funds is obviously the primary determinant of the marginal cost of lending via credit cards, and it is usually the only component of marginal cost that varies widely from quarter to quarter. Thus, a model of continuous spot market equilibrium would predict a substantial degree of connection between the interest rate charged on credit cards and the banks' cost of funds. However, Figure 1, which compares credit card interest rates with the cost of funds, displays stark empirical rejection of this prediction. Credit card interest rates were highly sticky during the period 1982–1989 and, in fact, were virtually constant.¹⁰

In this section, credit card interest rates are captured by two distinct sets of data: one aggregated and one disaggregated. The first set of data is the *Federal Reserve Bulletin* series for credit card interest rates, based on the Federal Reserve Board's quarterly survey of banks. Reported are arithmetic averages of each bank's "most common" rate charged during the first week of each mid-quarter month.¹¹ This series is plotted in Figure 1. The second set of data (and much of the empirical discussion of this and the next section) is derived from the author's own bank credit card survey (BCCS) of 58 of the largest bank issuers of credit cards. The first mailing (21 responses) asked primarily for pricing and cost data; it generated a quarterly interest rate series for 17 credit card issuers and an annual loan-loss series for 10 issuers. The follow-up

mailing (11 responses) included a request for direct profit calculations, which were provided by seven banks. Appendix A provides details of the construction of the BCCS. Table 2 includes the size distribution of banks that reported data. Respondents were promised anonymity.

The most aesthetically pleasing way for an economist to determine the cost of funds is to "let the market decide it." In the case of credit cards, this is feasible because of the phenomenon of credit card securitization. Consistently, during 1987–1989, credit-card-backed securities offered yields in the vicinity of 0.75 percent above those of Treasury securities with comparable maturities.¹² Meanwhile, the Visa systemwide average cardholder payment rate (i.e., cardholder payments as a percentage of outstanding balances) ranged from 13 to 17 percent per month during the years 1983–1987, implying an average maturity for credit card receivables of 6–8 months.¹³ To be conservative, I will define the cost of funds to equal the one-year Treasury bill yield¹⁴ plus 0.75 percent, averaged over each quarter. This series is also plotted in Figure 1.

The proposition that interest rates are sticky can be formally supported by regressing credit card interest rates on the cost of

¹²See, for example, "Credit Card Bonds are Hot, but Maybe Stingy on Yield," *Wall Street Journal*, April 16, 1990, p. C1; *Credit Card News*, Volume 1, Number 3 (June 15, 1988), p. 2, and Volume 1, Number 14 (November 15, 1988), p. 7; *Credit Card Management*, May/June 1988, p. 34.

¹³The source of the systemwide cardholder payment rate is Standard & Poor's *Asset-Backed Securitization Credit Review*, March 16, 1987, p. 19. Individual banks' prospectuses have reported cardholder payment rates of 9–23 percent per month, never implying an average maturity of more than one year (see list of prospectuses in Appendix B). This impression was substantiated by a trade-publication report quoting the chairman of FCC National Bank (First Chicago's Delaware credit card subsidiary, listed fourth in Table 1) as saying that his bank finances its credit card portfolio with a variety of financial instruments with combined maturities equivalent to a 145-day duration (*Credit Card News*, March 15, 1989, p. 2).

¹⁴*Federal Reserve Bulletin*, April 1990, table 1.35, line 21 (and previous issues).

¹⁰Indeed, the highest value reported in the *Federal Reserve Bulletin* series in the period 1982–1989 is 18.85 percent (first quarter, 1985) and the lowest value reported is 17.77 percent (fourth quarter, 1988).

¹¹Federal Reserve Board's G.19 statistical release, April 5, 1990; *Federal Reserve Bulletin*, April 1990, table 1.56, line 4 (and previous issues).

FIGURE 1. STICKY CREDIT CARD INTEREST RATES, 1982-1989

Notes: Credit card interest rate is the quarterly Federal Reserve System series; cost of funds is the quarterly one-year Treasury bill yield plus 0.75 percent.

funds. First, using the Federal Reserve series, an aggregate credit card interest rate is regressed on its own lagged value, the lagged cost of funds, and a constant. Second, a more thorough regression can be run using the author's BCCS series for the 17 individual banks: each bank's credit card interest

rate is regressed on its own lagged value, the lagged cost of funds, and a dummy variable for that bank. The results of these linear regressions are reported in Table 3. Note that, in the second regression, every coefficient has a *t* statistic of at least 6, while inclusion of additional variables with

Bank-13 dummy		4.99 (0.586)
Bank-14 dummy		4.88 (0.577)
Bank-15 dummy		5.50 (0.636)
Bank-16 dummy		5.22 (0.593)
Bank-17 dummy		6.17 (0.707)
Number of observations:	24	408
R ² :	0.96	0.937
Durbin h:	-0.69	0.10

Notes: CREDIT CARD INTEREST RATE is the dependent variable in each regression. COST OF FUNDS is defined as the yield on one-year Treasury bills plus 0.75 percent. Observe that there is no cross-firm variation in this variable, so that year dummy variables cannot be included in the second regression equation. Banks included in the author's bank credit card survey were assured anonymity. Numbers in parentheses are standard errors.

other lags tended to cause some coefficients to become insignificant. To aid in comparing the results of the two regressions, the Fed series is used only for the period 1982–1987; using 1982–1989 data yields the same conclusions.¹⁵

The coefficient on the cost of funds, while statistically significant in each of the two regressions, is economically insignificant. Whereas a competitive-spot-market model would predict a coefficient near 1, the regressions using aggregated and disaggregated data yielded coefficients of only 0.042 and 0.054, respectively. It takes many years for the price to adjust to changes in marginal cost when the rate of adjustment is only on the order of 5 percent per quarter.

B. Nonprice Competition .

The credit card industry has defended its high interest rates in the mid-to-late 1980's, in part, by asserting that the increased spread between the credit card interest rate and the cost of funds had been caused by an increase in the industry's rate of bad loans. The loan-loss data from the author's BCCS indicate that, in the period 1982–1987, the charge-off rate actually did increase roughly coincident with the increase in the interest rate spread (see Table 4). However, higher loan losses are an explanation for the higher interest rate spreads only if one believes that the latter are solely determined by costs. If credit card interest rates are determined otherwise, then *the causation may run in the reverse direction*: an increased interest rate spread may cause an increase in charge-offs.

Suppose, for example, that a bank can select both its interest rate and the default risk of its marginal customer. By choosing a higher marginal default rate, the bank increases its total number of loans but also its charge-off rate (the average default rate). Suppose that the bank first selects its interest rate and then its marginal default rate. Profit maximization requires the bank to set

¹⁵With the 1982–1989 *Federal Reserve Bulletin* series, one obtains a coefficient of 0.0439 on COST OF FUNDS₋₁, a coefficient of 0.864 on CREDIT CARD INTEREST RATE₋₁, and a constant of 2.06.

TABLE 4.—LOAN LOSSES ON CREDIT CARDS OF
TEN SURVEY BANKS DURING 1976–1987
(FEWER THAN NINE DURING 1976–1978 AND 1986–1987)
AND THE SPREAD BETWEEN CREDIT CARD
INTEREST RATES AND THE COST OF FUNDS

Year	Average charge-off rate (percentage)	Interest rate spread (percentage)
1976	1.15	10.57
1977	0.99	10.36
1978	1.27	8.11
1979	1.44	5.78
1980	2.04	5.08
1981	1.48	2.94
1982	1.67	6.42
1983	1.32	8.79
1984	1.36	7.69
1985	1.94	9.82
1986	3.01	11.55
1987	2.60	10.43

Source: Author's bank credit card survey (Appendix A, Table A1, questions 7 and 1).

its marginal default rate equal to the difference between the interest rate it charges and the marginal cost (net of defaults) of lending funds. (The net marginal cost should equal the cost of funds plus a constant that is fairly stable in the short run.) Thus, the prediction is that an optimizing bank should set its marginal default rate equal to the interest rate spread plus a constant.

Suppose now that there is an independent reason why credit card interest rates fail to fall when general market interest rates decline (for example, see Section VI, below). The logic of the previous paragraph dictates that loan losses will subsequently increase. If firms do not compete and drive price down toward marginal cost, they are likely instead to compete and drive marginal cost up toward price,¹⁶ in the form of issuing cards to less credit-worthy customers.

¹⁶A related argument was made in the context of airline regulation. George W. Douglas and James C. Miller (1974) argued that the Civil Aeronautics Board's price regulations, at a time when the introduction of jet engines reduced the fundamental cost of air transportation, led airlines to compete and drive their costs up to price by placing fewer passengers on a given airplane. The arguments differ in two important ways. First, in the airline industry, price rigidity may have been caused by price regulation, whereas with credit

III. The *Ex Post* Profitability of the Credit Card Market

As seen in Section I, the credit card market of the 1980's possessed most of the usual prerequisites for invoking the model of perfect competition. A perfectly competitive model would at least predict zero long-run economic profits for "marginal" firms. Moreover, since free entry into the industry is possible and no input appears to be in scarce supply,¹⁷ there is no credible source of rents to distinguish "inframarginal" firms from "marginal" firms. Thus, the competitive model would predict that all credit card issuers earn zero long-run economic profits. Many models of imperfect competition which preserve the free-entry assumption would also yield the zero-profit prediction.

By way of contrast, the interest rate stickiness documented in the previous section suggests that credit cards must become extraordinarily profitable whenever the cost of funds drops. Indeed, in this section, I will present a rather paradoxical set of data which indicates that returns from the credit card business were several times greater than the ordinary rate of return in banking during the years 1983–1988.

At the same time, this profitability data will help to assure that the above evidence of interest rate stickiness has been correctly interpreted. One might have thought to argue that price rigidity is consistent with

cards, there is price stickiness despite a deregulated environment. Second, under regulation, the airlines apparently competed away their profits.

¹⁷Free entry is a reasonable depiction of a credit card market in which 4,087 banks (and other deposit institutions) already issued their own Visa cards and a similar (largely overlapping) number issued their own MasterCard in September 1987. All of these institutions could legally offer accounts to customers anywhere in the United States. Nonmember institutions could join the Visa system by paying a fairly trivial entry fee: six dollars per million dollars in assets, plus one thousand dollars, according to a Visa official. (Only the assets of the subsidiary that issues the cards, and not the assets of the holding company, are figured into this formula.) Furthermore, it would seem strained to argue either that adjustment to the "long run" requires many years or that some input is in scarce supply, given the deluge of credit card solicitations made by banks in recent years.

competitive spot markets, if unobservable increases in quality exactly offset reductions in factor costs. The profitability data enable one to dismiss this possibility: profits, in fact, dramatically rose at the time that the cost of funds dropped.

It is possible to object to the following analysis on several grounds. First, the data reported, by their very nature, represent *ex post* profits. Perhaps (especially since the sample period is during a cyclical boom) the observed profits are merely a very favorable realization of a random variable whose *ex ante* returns were quite ordinary. Second, it might be thought that, while the credit card market was extremely profitable in the years 1983–1988, the market has now equilibrated and henceforth normal returns will be observed. Third, the profitability figures might be derived from accounting data that either are being misinterpreted or are systematically misstating true economic profits.

I consider each of these concerns elsewhere in the paper. In Section IV, I briefly discuss an additional source of evidence (the Federal Reserve System's functional cost analysis), which, while significantly less reliable than the other data (in this author's opinion), gives profits over a longer period that includes the previous cyclical downturn. In Section V, I introduce another independent set of data which examines resale prices of credit card portfolios between banks and finds that they trade at large premia. The latter data indicate that *ex ante* returns from credit cards are quite large and, since they are based on market valuations, should help allay any fears that the accounting data are being misinterpreted. Finally, it should be recalled from Table 4 that the interest rate spread was quite healthy except for a brief period around 1981 and that this brief spell of unprofitability can be attributed to banks not having yet established credit card subsidiaries exploiting the Supreme Court's *Marquette* decision. This episode does not seem likely to be repeated.

The *ex post* profit data reported and discussed in this section originate from three independent sources and were assembled by the author.

Bank credit card survey: The author's follow-up survey yielded profit calculations performed directly by executives of seven of the 50 largest bank issuers of credit cards.

Call reports: Profitability data for another nine of these issuers were extracted from call reports filed by the banks with the FDIC.

Prospectuses: Partial data on profitability for an additional eight large banks were obtained from filings with the SEC in connection with the sale of credit-card-backed securities.

Respondents to the author's survey were promised anonymity (but details of the construction are provided in Appendix A). The call reports and prospectuses are part of the public record. Table 2 reports the size distribution of banks included in each of the survey, call report, and prospectus samples.

A. An Illustrative Profit Calculation

As will be detailed in the next two subsections, earnings in the banking industry are usefully expressed as a percentage of assets: returns on assets are linked with returns on equity by the banking system's capital requirements. Before reporting summary profit figures for 15 and estimates for eight of the 50 largest issuers, I will examine in detail the components of revenues and costs for one individual credit card issuer. I consider here Maryland Bank, N.A. (MBNA), the Delaware-based credit card arm of MNC Financial, which is ranked seventh in Table 1.¹⁸ This institution was selected because more public information exists on its credit card operations than on any other bank's: MBNA, which is required to file its own call report, has credit card loans exceeding 92 percent of its assets, and it has also made several credit-card-backed securities offerings.

¹⁸MNC Financial is the 39th largest U.S. bank holding company and the corporate parent of Maryland National Bank, the largest commercial bank in Maryland. MBNA was founded in Newark, Delaware, in 1982, apparently to avoid Maryland's usury law. See also the text near footnote 9.

TABLE 5—COMPONENTS OF PROFITS FOR MARYLAND BANK, N.A.

Components	1985	1986	1987
Finance charges	16.66%	14.92%	13.21%
Annual fees	1.40%	1.58%	1.29%
Other customer charges	1.10%	1.42%	1.17%
Interchange fees	3.06%	3.00%	2.92%
Total revenue:	22.22%	20.92%	18.60%
Interest expenses	9.57%	7.80%	7.13%
Noninterest expenses	4.47%	4.71%	4.87%
Net charge-offs	1.09%	1.77%	1.80%
Total cost:	15.13%	14.28%	13.80%
Return on assets (pretax profits expressed as a percentage of outstanding balances)	7.09%	6.63%	4.80%

Sources: Consolidated reports of condition and income (call reports), prospectuses, and registration statements for Maryland Bank, N.A.

MBNA's credit card operations (and their profitability) are fairly typical of major issuers, with the exception that the bank has stressed the concept of "affinity credit cards," whereby cards are marketed to members of professional organizations, fraternal orders, and cause-related groups (with the organizations' endorsements). As a consequence, its interest rates are somewhat lower and its customers are somewhat more credit-worthy than average. Indeed, it may interest readers that, during the period when this article was undergoing the journal's review process, MBNA's marketing agent proposed to establish an official American Economic Association Visa card. This card would have carried a \$20 annual fee (\$40 for a gold card) and an 18.9-percent annual fee; the AEA would have received \$1 for each account opened, \$3 for each account renewed, and \$0.25 per retail transaction. MBNA's agent estimated that 1,000 cards would be issued, generating \$13 in revenue per card per year for the AEA. However, the AEA's executive committee, concerned that the AEA "would be viewed as endorsing a specific credit card by entering into such a contract," voted against establishing the affinity card program.¹⁹

¹⁹Draft minutes of the March 23, 1990, meeting of the AEA Executive Committee; Report of the Secre-

An item-by-item profit calculation for MBNA is displayed in Table 5. As is typical for credit card issuers, the single largest component of revenue is the finance charge (which, for MBNA, derives from annual percentage rates of 14.5–18.9 percent, depending on the account). Despite the fact that the bank provides a 25-day grace period during which no finance charge is assessed if the account balance is paid in full, more than 80 percent of the bank's credit card outstanding balances do accrue interest.²⁰ The drop in finance-charge revenues displayed in Table 5 is largely attributable to the bank's decision to reduce the interest rates on some of its accounts during 1985–1987.

MBNA also derives direct customer revenues from the annual fee and other customer charges (e.g., \$15 late payment, over-limit, and returned-check charges). Indirect revenues are derived from the interchange fee, the portion of the merchant discount that is paid to the customer's bank. It is worth reemphasizing that the price sched-

tary to the Executive Committee. I thank Orley Ashenfelter and C. Elton Hinshaw for providing this information.

²⁰A good rule of thumb mentioned in credit card trade publications is that 90 percent of an issuer's overall outstanding balances accrue interest. See the discussion in Section VI-C.

ules that determine direct customer revenues are set entirely at the bank level; only the interchange fee is set systemwide by the MasterCard and Visa organizations.

Costs can be divided among interest expenses, operating expenses, and loan losses. Interest expense is determined by market interest rates and thus is relatively uniform across banks, as a percentage of outstanding balances. Noninterest expenses, which include employee salaries, occupancy, equipment, and data processing, are also available from the banks' direct reports and call reports. These noninterest expenses typically equal 4–6 percent of outstanding balances for large issuers and are mostly (but not entirely) a proper component of total cost. The exception is that the expense of generating a new account (mostly advertising and marketing costs) should properly be considered an investment and thus should be amortized over a longer period. Nevertheless, I have no systematic way to separate out these new-account expenses from banks' profits; consequently, I use the entire "noninterest expense" in my computations. Observe that this will tend to overstate costs and understate the returns on assets and equity. Loan losses are best measured by the bank's "net credit losses" or "net charge-offs," which represent the outstanding balances that the bank newly treats as uncollectable.²¹ (Typically, a bank charges

off a balance six months after the cardholder ceases payment on an account.) MBNA's charge-off rate is 1–2 percent lower than that of many large credit card issuers.

As seen in Table 5, MBNA's *pretax* return on assets (ROA) in credit cards equaled 7.09 percent in 1985, 6.63 percent in 1986, and 4.80 percent in 1987. The 1987 figure, for example, interacts with a 42-percent tax rate to yield an *after-tax* return on assets of 2.78 percent. For evidence of the accuracy of this computation, one need look no further than MNC Financial's 1987 annual report:

Our credit card operations had another outstanding year. Maryland Bank, N.A. (MBNA) is by no means typical of the industry, which often is the target for criticism and concern. Over the past five years, MBNA has been one of our fastest growing businesses. With \$2 billion in outstandings, it continues to be a low cost, high-volume producer with chargeoffs of about 2%—about half of the industry average. We think most investors will find it hard not to be impressed with a business that earns more than 2.5% (after-tax, 1987) on assets.²²

By way of comparison, the bank holding company as a whole earned a 1.36-percent ROA before taxes and a 1.00-percent ROA after taxes in 1987.²³ The holding company, minus its credit card business, earned less than a 0.80-percent ROA after taxes in 1987.

B. *The Ordinary Rate of Return in the Banking Industry*

The pretax return on assets for all U.S. commercial banks during the sample years

²¹The follow-up bank credit card survey specifically asked for the bank's "net credit losses" (see Appendix A). The item used from call reports is the "net charge-offs." An alternative measure of losses that could have been used from the call reports is the bank's "provision for loan losses," which is often higher and which may include an allowance for loans that the bank (statistically) expects to charge off in the future. There are two reasons not to use the figure for provision. First, credit card accounts incur most of their charge-offs in the initial two years of the life of the account. Hence, the difference between "provision" and "net charge-offs" (and, in fact, some of "net charge-offs" itself) typically represents an expense of generating new accounts and, as in the case of marketing expenses, should properly be treated as an investment which is amortized over a longer period. Using "net charge-offs" mitigates this effect and gives a better measure of cost. Second, "provision" is a quantity that is easily manipulated by the bank: one can use a large loss provision to defer income taxes or a small

loss provision to report high current earnings. "Net charge-offs" is less manipulable. The Federal Reserve System's functional cost analysis also uses "net credit losses" in earnings computations.

²²MNC Financial, 1987 Annual Report (dated March 1988), p. 4.

²³MNC Financial, 1987 Annual Report (dated March 1988), p. 1.

equaled 0.85 percent in 1983, 0.83 percent in 1984, 0.90 percent in 1985, 0.80 percent in 1986, 0.28 percent in 1987, and 1.14 percent in 1988.²⁴ Taking into account that some areas of banking were effectively taxed at a lower rate than the credit card businesses (which were taxed at close to the statutory tax rates of 34–46 percent during this period), it is probably correct to think of 1.20 percent as the ordinary (pretax) return on assets in the banking industry at large.

The relationship between the ordinary rate of return on assets and the ordinary rate of return on equity in the banking industry depends on the capital requirements of banks. For the period 1983–1988, the capital requirement equaled about 6 percent of assets. First, in 1984–1985, U.S. banking regulators promulgated capital standards for all commercial bank activities equaling 6 percent of assets for total capital (and 5.5 percent of assets for primary capital).²⁵ Second, *actual* total equity capital for all insured U.S. commercial banks equaled 5.96 percent of assets in 1983, 6.01 percent in 1984, 6.17 percent in 1985, 6.21 percent in 1986, 6.06 percent in 1987, and 6.10 percent in 1988 (with substantially smaller percentages for the larger banks).²⁶ Dividing an ordinary (pretax) return on assets of 1.20 percent by a capital requirement of 6 per-

cent would imply an ordinary (pretax) return on equity of 20 percent per year.

C. Computations of Ex Post Profitability for 15 Large Issuers

Several different summary measures of (*ex post*) profitability are presented in Tables 6 and 7. The first measure of return on assets, ROA (reported), is precisely the calculation we illustrated above for MBNA. One potential flaw in this calculation is that it relies on the bank's own reported cost of funds. The problem here is that some banks may not have been allocating the true opportunity cost of their low-cost core deposits (e.g., passbook accounts and non-interest-bearing checking accounts) to their credit card businesses; in that event, some of the profits allocated to the credit card operations would in fact be attributable to the branch banking business.

This difficulty is easily remedied by replacing each bank's reported interest expense with the standardized index of the cost of funds defined and defended in Section II. My second measure of return on assets, ROA (adjusted), is computed by using an interest expense of COST OF FUNDS applied to the nonequity portion of assets; thus, interest expense as a percentage of assets equals 94 percent of COST OF FUNDS.²⁷ If anything, my adjustment tends to reduce systematically the reported returns; observe in Table 7 that ROA (reported) exceeds ROA (adjusted) in four out of six years.

The return on equity is computed in two different ways in Table 7. The first and most obvious measure, ROE (actual cap), merely divides (pretax) profits by the actual capital residing in the credit card bank at the previous year's end. (Since each bank in Table 7 is a legally distinct entity, its capital is a

²⁴*Federal Reserve Bulletin*, July 1989, p. 462 (table 1), and July 1988, p. 404 (table 1). The substantially lower earnings for 1987 reflect the decision of large banks to set aside large sums to cover troubled loans to developing countries. Excluding international operations, the banks' rates of earnings in 1987 appear to have very slightly exceeded those of 1986.

²⁵At this writing, bank capital standards are scheduled to rise, by international agreement, to 8 percent of total risk assets in 1992. At the same time, the new and rapidly expanding practice of securitizing credit card assets has the effect of removing the credit card accounts from banks' balance sheets, thus reducing the effective capital requirement.

²⁶*Federal Reserve Bulletin*, July 1989, pp. 474–83 (table A.1), and July 1988, p. 405 (table 2). For money-center banks, equity capital equaled 4.30, 4.56, 4.69, 4.78, 4.33, and 4.42 percent of assets in the respective years. For other banks with \$5 billion or more in assets, equity capital equaled 4.76, 5.08, 5.42, 5.50, 5.29, and 5.29 percent of assets in the respective years.

²⁷ROA (adjusted), as computed from the call report data, also contains a second, minor adjustment: to the extent that a bank has purchased credit card portfolios from other banks at a premium (see Section V) and subtracted a portion of the premium from its profits, ROA (adjusted) adds it back in.

TABLE 6—RETURN ON ASSETS AND RETURN ON EQUITY (PRETAX) BASED ON DIRECT REPORTS OF CREDIT CARD ISSUERS

Source: Author's bank credit card survey (Appendix A, follow-up survey, Table A2, question 4).

well-defined quantity.²⁸) However, ROE (actual cap) is not an entirely appealing measure of return on equity. Observe that, for example, the quantity of capital that resides in Citibank South Dakota (as opposed to the principal New York bank or the parent holding company) is relatively discretionary and arbitrary. Indeed, one finds that the credit card subsidiary of a bank is often relatively undercapitalized in

some years and relatively overcapitalized in other years. While ROE (actual cap) is reported in Table 7, this datum should probably be interpreted skeptically.

A preferred measure to consult is ROE (adjusted), which is computed simply by dividing ROA (adjusted) by 6 percent. The logic behind this measure is that, as argued above, the capital requirement during the sample period has in practice equaled about 6 percent of assets, uniformly across banking activities. Thus, it seems more sensible to impute the 6-percent capital standard to all credit card assets than to rely on a capriciously chosen bank number. ROE (adjusted), which is the last measure provided in Tables 6 and 7, is probably the most informative to examine and discuss.

²⁸Data on credit card capitalization for the firms reported in Table 6 do not exist. In fact, six of the seven firms operate their credit card businesses within the same bank as their other lines of business, so there does not exist capital separately allocated to the credit card business; "actual capital," then, is not a well-defined quantity.

Source: Consolidated reports of condition and income (call reports).

^aBank's credit card portfolio was acquired in 1986–1987; see Table 9.

By the standards of the previous subsection, the rates of return reported in Tables 6 and 7 are extraordinary. All seven banks that provided direct reports of profit data for 1985 and six out of seven that provided direct reports for 1986 attained (pretax) returns on equity exceeding 100 percent per year! The sample average for these banks also exceeded 100 percent in 1987 and exceeded 80 percent in 1984 and 1988. The profit figures drawn from call reports are not quite as large but still are generous. Sample averages for return on equity exceeded 90 percent in 1985 and 1986 and exceeded 70 percent in all remaining years. It is unclear why the direct reports provided returns on equity systematically 10–20 percentage points higher than the call reports. Part of the reason is undoubtedly that firms that established separate credit card banks sustained higher rates of growth in assets, concealing a greater investment in new accounts in the cost data.²⁹

D. *Estimates of Ex Post Profitability for an Additional Eight Issuers*

The computations of the preceding subsection were performed for 15 credit card issuers for whom all components of profits were known. If the data set is expanded to include banks for whom most, but not all, components are known, it is possible to make statements about an even larger proportion of the 50 largest firms.

Eight additional banks, including Bank of America (ranked third largest), First Chicago (ranked fourth), and Manufacturers Hanover (ranked fifth), have disclosed significant information in connection with the issuance of credit-card-backed securi-

ties.³⁰ All items in Table 5 except noninterest expenses (i.e., non-credit-related operating expenses) and interchange fees are thus known for these issuers; moreover, these two missing items (unlike customer revenue and net charge-offs) do not vary widely among comparable banks. I approximate their rates of profit by assuming that the additional eight issuers' operating expenses and interchange fees are equal (as a percentage of assets) to those for which I have direct knowledge. Making the same normalizations for these banks as before, I obtain conservative³¹ average pretax returns on equity (adjusted) of 65 percent in 1984 (three banks), 87 percent in 1985 (five banks), 92 percent in 1986 (all eight banks), 76 percent in 1987 (seven banks), and 62 percent in 1988 (six banks). It is worth noting that all of these numbers are quite close to the adjusted ROE's of Table 7, and all exceed 60 percent per year.

The sample from which a conclusion about profitability can be based is rather large. Exact computations or good estimates are available for as many as 23 of the 50 largest issuers of bank credit cards, with approximately 50 percent of industry market share (by outstanding balances). Included in the sample are all of the five largest firms.

The conclusion drawn from Table 6, Table 7, and the numbers stated two paragraphs above is quite straightforward. As argued above, the ordinary (pretax) return on equity in banking is on the order of 20 percent per year. Credit card businesses earned annual returns of 60–100 percent or more during the years 1983–1988. Plastic earned

²⁹An anonymous referee correctly observed that the return on assets derived from direct reports uses credit card balances in place of total assets as denominator. However, the call report data show that this does not appreciably overstate the true return on assets. Premises and fixed assets typically equaled no more than 0.3–2.0 percent of a credit card bank's total assets, while credit card loans generally exceeded 97 percent of total assets.

³⁰See Appendix B for a listing of the relevant registration statements. While information in connection with credit-card-backed securities is also available for Citibank, Maryland National, and Lomas Bank U.S.A., these banks are already represented in Table 7 and so are excluded from the current discussion.

³¹Some prospectuses report gross rather than net charge-offs, reducing the reported level of profits. Furthermore, the figures I used for noninterest expense (generally 5.40 percent of outstanding balances) seem to be on the high side.

strongly positive economic profits: the credit card business earned 3–5 times the ordinary rate of return in the banking industry.

IV. Additional Evidence from the Functional Cost Analysis

The previous discussion has focused on the profitability of the 50 largest issuers of credit cards during the period 1983–1988. It is interesting to consider briefly whether the conclusions change when the sample of banks and the time period examined are extended.

This exercise should help address two potential questions.³² First, suppose it were the case that the smaller players in the market earned only the ordinary rate of return on capital. Then, the reader may be troubled by the possibility that the larger firms may possess some unobservable attributes which are not reproducible (e.g., “business acumen”) that earn positive rents. (However, there would still remain the question of why 50 larger firms is not enough for competition.) On the other hand, if literally hundreds of firms, including small regional banks, all earn supranormal profits, it becomes much more convincing that none of these firms possesses anything special (except for a base of customers). Second, the reader may be concerned that the article has focused on a period of time that coincides with a cyclical boom in the national economy. Part of this selection of time is unavoidable: as observed in Section I, the credit card market did not become functionally deregulated until about 1982; much of the earlier experience can be dismissed as the result of state usury ceilings. In addition, my reliable sources of data only extend back to this time. Nevertheless, it may be helpful to present some (albeit imperfect) data which provide a better sense of the extent to which profitability is cyclical.

Both of these points can be discussed by introducing an additional source of data: the Federal Reserve System’s functional cost analysis (FCA). In this author’s opinion, the FCA data are considerably less reliable than the other profitability data utilized in this article, and so they should be interpreted cautiously. There has been little effort to track the same banks from year to year; in particular, the sample size has dropped approximately 60 percent from 1976 to 1988. One also obtains the sense that the accounting data provided by the smaller banks in the Fed’s sample do not do as good a job as the other sources of properly allocating costs between credit cards and the banks’ other lines of business. Nevertheless, it is the only available source of profitability figures for the smaller banks and for earlier years.

The average charge-off rate and the average return on assets from the functional cost analysis for the years 1976–1988 are displayed in Table 8. The typical credit card issuer represented in the FCA sample is ranked approximately between number 300 and 400, nationally, by outstanding balances. The first observation to make is that the charge-off experience of the smaller banks is broadly consistent with what has already been seen in Table 4. As before, loan losses remained tightly in the 1–3 percent per year range.

Since bank credit card operating expenses are believed to exhibit increasing returns to scale over a range (Christine Pavel and Paula Binkley, 1987), one would expect that the return on assets would be somewhat lower than that reported above for the largest issuers. Indeed, during the period 1983–1988 (for which numbers are available for both the smaller issuers and the larger issuers), the smaller banks earned only about 60 percent of the returns of the larger banks and only about 50 percent of the “excess” returns of the larger banks. Nevertheless, the returns do remain substantially above the ordinary rate of return in banking; over the longer period that includes the cyclical downturn, the smaller issuers still appear to have earned roughly twice the ordinary rate of return in banking.

³²These are questions that were raised by two anonymous referees. I am grateful to them for raising these issues.

TABLE 8—RETURN ON ASSETS FOR SMALLER CREDIT CARD ISSUERS, 1976–1987, FROM THE FEDERAL RESERVE SYSTEM'S FUNCTIONAL COST ANALYSIS (FCA)

Year	Number of banks in sample	Average charge-off rate (percentage)	Average return on assets (percentage)
1976	236	1.48	2.72
1977	224	1.41	3.07
1978	181	1.66	2.44
1979	184	1.92	1.60
1980	139	2.54	-1.52
1981	128	2.25	0.97
1982	138	1.93	2.40
1983	102	1.58	2.37
1984	98	1.24	3.45
1985	85	1.81	3.97
1986	76	2.33	3.28
1987	93	1.65	3.94
1988	89	2.51	2.72

Notes: Data are taken from the Board of Governors of the Federal Reserve System's *Functional Cost Analysis, National Average Report, Commercial Banks, Credit Card Function (Card Banks), 1976–1988*. The third column represents "net credit losses + net fraud losses"; the fourth column represents "net earnings after cost of money." Both columns are expressed as percentages of average outstanding balances on credit cards and are weighted averages based on individual banks' average outstanding balances. Earnings are before taxes. In Section III-B, it is argued that the ordinary return on assets is approximately 1.20 percent.

These numbers may significantly understate the profitability of credit cards over the entire business cycle. First, banks have the ability (with some lags) to increase their lendings at cyclical peaks and to cut their lendings at cyclical troughs. (This is not merely conjectural: their ability to act in this way is fairly apparent from data on banks' levels of outstanding balances.) Thus, greater weight should be placed on the returns in boom years. Second, as emphasized above, banks took some time to learn how to exploit the December 1978 *Marquette* decision and so were hindered in their ability to react to climbing costs of funds during 1979–1981. The learning has now been done, and so the 1979–1981 earnings experience is unlikely to be repeated.

V. The *Ex Ante* Profitability of the Credit Card Market

As was emphasized in the fourth paragraph of Section III, there is good reason to be a bit skeptical of *ex post* profitability data. In this section, I will seek (as directly as possible) to examine *ex ante* returns of the credit card market.

Suppose that bank I has issued credit cards to consumers and has \$*X* in balances outstanding on these accounts. The question one may ask is how much bank II will pay bank I to acquire these accounts, as a function of *X*. If the credit card accounts were expected, *ex ante*, to pay the ordinary rate of return on capital (or the risky equivalent), then the transaction would presumably occur at about *par* (i.e., bank II would pay bank I the same \$*X* to assume the accounts). If there existed a substantial probability that consumers would default on the loans and if the contractual interest payments and fees did not adequately compensate for this eventuality, then bank II could presumably acquire these loans at a *discount*.³³ Finally, only if the owner of the credit card accounts could be expected to earn above the ordinary rate of return on capital would the accounts sell at a *premium* above \$*X*; then, the future stream of positive economic profits would be capitalized in the transaction price. If bank II pays bank I \$120 million for accounts on which only \$100 million is owed, I will refer to this as a 20-percent premium.

The model of perfect competition predicts that resales of credit card accounts will occur at *par*, in the long run.³⁴ During the

³³For a good example of discounted loans, consider the resale among banks of loans to developing countries; in the late 1980's, such transactions frequently occurred at prices well below 50 percent of face value.

³⁴One may argue that there should exist a premium representing the cost of establishing an ongoing business. An important point to observe is that, typically, when a bank acquires another bank's credit card portfolio, it transfers the acquired portfolio over to its own preexisting offices and processing facilities. That is to say, basically the only portion of the "ongoing business" that the acquirer desires is the customer base. In the

equilibrating process toward the long run, the theory would tolerate discrepancies from par but firmly predicts that resale prices will monotonically converge toward par. However, a systematic failure of competition in the credit card market (as suggested by the profit figures in the previous sections) would require, to the contrary, that interbank transactions persistently occur at substantial premia. Fortunately, there exist real data against which to test these two divergent predictions.

The premia paid by banks in credit card deals during the years between 1984 and

early 1990 are compiled in Table 9. All 27 such interbank transactions for which I could find a public disclosure of the premium are reported. The average premium in Table 9 equals 20 percent; all transactions occurred at premia between 3 percent and 27 percent. There is no tendency for the premia to vanish monotonically; if anything, the largest premia are associated with the most recent transactions.

The resale data clearly suggest that, at this writing in 1990, and throughout the period of 1984–1988, the *ex ante* expected economic profits (adjusted for risk) on existing credit card accounts were substantially positive. The premium that is theoretically justified for credit card accounts depends on a number of parameters for which I possess no data. However, Table 10 presents the premia that are justified for a

model of perfect competition, customers inexorably gravitate to the low-priced firm; the phenomenon of “captive” or “loyal” customers does not exist. Thus, an existing base of customers, by itself, should draw no premium.

TABLE 10—PREMIA IN RESALE OF CREDIT CARD ACCOUNTS JUSTIFIED BY VARIOUS EXPECTED LIFETIMES OF ACCOUNTS, ANNUAL GROWTH RATES OF OUTSTANDINGS PER ACCOUNT, AND CREDIT CARD PROFITABILITY (AS A MULTIPLE OF ORDINARY RATE OF RETURN)

Expected lifetime (years)	Multiple of ordinary rate of return	Premia (percentage)			
		10-percent growth	20-percent growth	30-percent growth	40-percent growth
2	1	0.00	0.00	0.00	0.00
	2	2.40	2.51	2.62	2.73
	3	4.80	5.02	5.24	5.45
	4	7.20	7.53	7.85	8.18
	5	9.60	10.04	10.47	10.91
4	1	0.00	0.00	0.00	0.00
	2	4.80	5.50	6.27	7.15
	3	9.60	10.99	12.55	14.29
	4	14.40	16.49	18.82	21.44
	5	19.20	21.98	25.10	28.58
6	1	0.00	0.00	0.00	0.00
	2	7.20	9.05	11.38	14.30
	3	14.40	18.10	22.76	28.60
	4	21.60	27.15	34.15	42.90
	5	28.80	36.19	45.53	57.20

Calculations: For N = expected lifetime of credit card accounts, g = annual growth rate of outstandings per account (during lifetime of account), $r = 0.10$ = interest rate used by bank in discounting, ROA_{cc} = return on assets from credit cards, $ROA_{ord} = 0.012$ = ordinary return on assets in banking, and Φ = premium in resale of credit card accounts (as proportion of outstanding balances at time of sale),

$$\Phi = (ROA_{cc} - ROA_{ord}) \sum_{K=0}^{N-1} \left(\frac{1+g}{1+r} \right)^K$$

number of sets of assumptions. The expected "lifetime" of an account represents the number of years that a bank anticipates that the consumer will continue to maintain his credit card account, under the same borrowing patterns and the same rate of profitability. The growth rate represents the rate at which a bank believes that the outstanding balances on the acquired credit card accounts will increase during their lifetime; meanwhile, I assume that the bank discounts using a 10-percent interest rate. The ordinary rate of return in banking is taken, as above, to be a 1.20-percent annual pretax return on assets. The calculations in Table 10 implicitly assume that the seller of credit card accounts receives all of the gains from trade; if (as one may reasonably expect) the buyer also obtains some gains, then the indicated premia require still higher rates of return from credit cards. Thus, these should only be taken as lower bounds on implied profitability.

As Table 10 indicates, it is difficult to justify the recent flurry of premia in the range of 23–27 percent unless returns equaling at least three times the ordinary rate of return in banking are expected to persist. Even with the optimistic³⁵ assumptions that the typical account will be maintained for six years after the acquisition and that the outstanding balances will grow at an overly fast 40 percent per year during that period, profits at three times the ordinary rate of return lead to a premium of only 28.60 percent. The more typical premium of 20 percent, in conjunction with reasonable projections of lifetime and

³⁵For example, at the date of the First RepublicBank transaction, First Republic's average outstanding balance per active account equaled about \$1,000, roughly the national average. A 40-percent growth rate for five years would increase the average outstanding balance by more than a factor of five, justifying the adjective "optimistic."

growth, still requires profitability of three or more times the ordinary rate of return in banking. Finally, it should be observed that one of the lowest reported premia (Colonial National Bank, at 11 percent) involved credit cards with a mean outstanding balance per active account equaling \$2,000, or about twice the national average. It would be rather unrealistic to project growth of more than 10 percent per year on these balances, which still suggests profitability about three times the ordinary rate.

I will make three final notes on *ex ante* profitability. First, the reader may still worry that, since credit card debts are unsecured, charge-off rates will jump and profitability will plummet in the next recession. Some historical data should allay these concerns. In Tables 4 and 8, one may trace back net charge-offs through the last recession. One finds, for these samples, that charge-offs in the early 1980's increased only fractionally above prior years and peaked at only about 2.5 percent of outstandings. Independently, Visa system-wide data traces back credit losses through the last two recessions, and finds (annualized) quarterly charge-off rates peaking at 3 percent in 1974 and again in 1980.³⁶ Solicitation of new accounts, and not cyclical phenomena, are the important contributors to credit card charge-offs (see also Section II-B, above).

Second, the reader may have noted that substantial premia (although not as large as for credit card accounts) have also been reported in sales of regional banks. If anything, this makes the credit card premia even more surprising. The premia for regional banks represent "goodwill," which economists should interpret as economic rents derived from local monopolies in banking. By way of contrast, the national market for credit cards has no local monopolies, so the competitive model predicts that "goodwill" should equal zero.³⁷

Third, the magnitude of resale premia may be taken as clear evidence that players within the industry itself attach little credence to the possibility that the credit card market will begin to behave competitively in the years immediately following 1990. (If, for example, it were believed that competition would drive economic profits to zero in two years, this would be the same as using an expected "lifetime" in Table 10 of two years.) Data in the previous section showed that the zero-profit prediction failed in the years 1983–1988. If bankers have had rational expectations in their acquisitions of accounts, then supranormal profits should persist for at least the period 1990–1993. Credit card profits will then have equaled three times the ordinary rate of return for more than an entire decade, certainly an extended adjustment period to the long run!

VI. Theoretical Explanations for the Failure of Competition

In this section, I briefly outline some theoretical models that lead to predictions of price stickiness and positive economic profits. I also discuss some empirical evidence related to these theories. Formal modeling details are available in Ausubel (1988), the working-paper precursor of this article.

A. Search/Switch Cost Theories

One of the common explanations offered for high credit card interest rates is that consumers find it difficult to locate banks offering favorable terms. Indeed, the U.S. Congress enacted legislation in October 1988 that requires all issuers to disclose their interest rates, fees, and grace periods on solicitations and applications; supporters of the bill articulated the rationale of enabling consumers to shop around for the least expensive card, (i.e., of reducing consumer search costs).

Models with search costs may plausibly lead to sticky interest rates and positive

³⁶The source of system-wide net charge-offs is Standard & Poor's *Asset-Backed Securitization CreditReview*, March 16, 1987, p. 19.

³⁷In addition, a regional bank may own appreciated real estate whose book value equals historic cost, also contributing to reported premia over book value. The

credit card transactions typically do not involve any real assets that have appreciated in value.

profits. While other explanations also exist for price stickiness (e.g., menu costs; see e.g., Julio J. Rotemberg and Garth Saloner, 1987), there is good reason to focus on search/switch costs in the credit card market. Banks have recently begun to use marketing techniques that are consistent with this type of story. Issuers frequently waive the annual fee for a fixed period of time and, in a few cases, offer "to pay you up to \$100 when you transfer your other credit card balances" to their MasterCard or Visa accounts.³⁸ The focus of federal regulation on disclosure provides additional support for the search-cost explanation.

In models that are thematically related to that of Peter Diamond (1971) and subsequent papers, there may exist a continuum of symmetric equilibrium prices that are consistent with any given marginal cost.³⁹ Therefore, the historical price may continue to be an equilibrium even after a change in marginal cost. That is, price stickiness may be consistent with equilibrium. (Detailed analysis of a straightforward model that yields this conclusion is provided in the working-paper version of this paper. It should also be noted that a formal model of switch costs [see e.g., Ausubel, 1984; Joseph Farrell and Carl Shapiro, 1987; Paul Klemperer, 1987] can result in conclusions similar to those from search-cost models.)

Such models also provide a reason why supranormal profits may not be competed away. If prices remain sticky when costs drop, firms begin to earn supranormal profits. Profits continue at high levels until prices unstick, costs rise again, or the customer base is sufficiently eroded. The logic is that, if consumers face search costs in locating (or face switch costs in moving to) lower-priced firms, then higher-priced firms can hold onto many of their (captive) customers despite their high prices. As suggested

above, competitors may try to defeat this inertia by offering sign-up bonuses to new customers, but to the extent that such devices are limited in their effectiveness and practicality, firms may derive supranormal profits from their existing customer base. Finally, observe that this story enables a firm with a base of "loyal customers" to earn supranormal profits despite competition both from other existing firms (who want to increase their own customer bases) and from new entrants (who want to establish customer bases).

The credit card industry is a business where both search costs and switch costs are likely to be especially prevalent. They include: (a) the information cost of discovering which banks are offering lower interest rates; (b) the cost in time, effort, and emotional energy in filling out an application for a new card (and possibly getting rejected); (c) the fact that the card fee is usually billed on an annual basis, so that if one switches banks at the wrong time, one forgoes some money; (d) the perception that one acquires a better credit rating or a higher credit limit by holding the same bank's card for a long time; and (e) the time lag between applying for a card and receiving one.

While credit card consumers undoubtedly face some positive level of search costs and switch costs (and this gives entirely rational justification for the observed market behavior), there remains an empirical question as to whether the actual search/switch costs are of sufficient magnitude to justify what is observed. A typical credit card account in the late 1980's had an outstanding balance slightly over \$1,000 (see Section VI-C and Table 11, below). The prevailing premium on resales of these accounts (see Section V and Table 9) then translates to almost \$250 per account. In a search/switch cost equilibrium, one would expect the resale premium to equal the search or switch cost; yet it is hard to imagine that the costs enumerated in the previous paragraph are the monetary equivalent of \$250! Given this caveat, it is not at all clear that search or switch costs could provide a full explanation of observed market behavior; it would be valuable for future empirical work (using data at

³⁸ The quotation is taken from a direct-mailed solicitation, dated April 1989, from Imperial Savings (approximately the fifth-largest S&L issuer of credit cards).

³⁹ Mitchell Berlin and Loretta J. Mester (1988) tested and rejected a (very different) model, in which consumer search costs were used to try to explain price dispersion in credit card interest rates.

TABLE 11—PERCENTAGE OF CUSTOMERS WHO AVOID FINANCE CHARGES AND AVERAGE OUTSTANDING BALANCES PER ACTIVE ACCOUNT

Year	Percentage of customers who avoid finance charges	Number of banks reporting percentage of customers	Average outstanding balance of active account	Number of banks reporting outstanding balance
1979	31.8	6	\$523	7
1980	28.7	6	\$590	8
1981	21.9	6	\$660	8
1982	21.0	6	\$726	9
1983	22.8	8	\$711	10
1984	21.9	10	\$852	10
1985	21.4	12	\$1,014	12
1986	24.6	14	\$1,018	17
1987	27.6	9	\$1,038	10

the customer level) to examine this question.

B. *A New Adverse-Selection Theory*

I now propose an adverse-selection theory that relies on a very specific form of irrationality (which will be given some indirect empirical support in the following subsection). Since a credit card is really quite an expensive medium on which to borrow, I posit a class of consumers who do not intend to borrow on their accounts but find themselves doing so anyway.⁴⁰ Consumers in this first class are precisely the best customers from a (rational) bank's viewpoint: they borrow at high interest rates, yet they eventually (in most cases) repay their loans. At the same time, these consumers are unlikely to be responsive to any interest rate cut by a bank, as they do not intend to borrow at the outset.

I also assume that there is a second class of consumers who fully intend to borrow on their credit card accounts. These are the consumers who are bad credit risks and thus lack less expensive alternatives; bank cards are their best sources of credit. Consumers in the second class are less than ideal from

a bank's perspective: they borrow large sums but often default. Insidiously, these customers are more likely to comparison shop on interest rates than the better credit risks, as they actually plan to be paying substantial finance charges. (There is also a third class of consumers, the "convenience" users, whom I can neglect in this discussion. They never borrow on their credit cards and, thus [rationally], are completely unresponsive to interest rate differentials.)

Given this environment of consumers, banks will be hesitant to compete in the interest-rate dimension, as a lower price on credit would disproportionately draw the class of consumers who plan to utilize their credit lines. If consumer behavior along these lines is superimposed on a search-cost model, the tendency toward interest-rate stickiness that was described in the preceding subsection becomes magnified (see Ausubel [1988], the working-paper precursor of this article, for a formalization of this story).

Such reasoning additionally provides an explanation for the apparent cross-subsidy from the transaction function to the credit function of the bank card.⁴¹ Banks only face adverse selection when they compete on the

⁴⁰It may be possible to rationalize these consumers' behavior by assuming that they face a commitment problem: consumers cannot commit their future selves not to borrow.

⁴¹Credit card issuers appear, at best, to break even on their "convenience" users and, perhaps, lose money on them. Meanwhile, issuers earn supranormal profits on consumers who borrow on their cards.

credit-sensitive portions of prices; they do not face adverse selection when they unilaterally improve the terms facing customers who charge purchases on their credit cards but do not borrow beyond the due date on their bills. This would seem to be a powerful explanation why essentially all large issuers offer a substantial grace period on new purchases (provided that the previous balance was paid in full). It also suggests why issuers hardly ever impose transaction charges, often ask for rather small (and, sometimes, zero) annual fees, and occasionally offer transaction subsidies (for example, rebates on purchases or frequent-flyer miles). At the same time, issuers may install punitive prices for bad credit risks: for example, disproportionately high fees for missing a minimum required payment. Since such large proportions of revenues are derived from finance charges, while the adverse-selection argument implies that the interest rate should not be used as an instrument for competition, it becomes much more difficult for credit card issuers to compete away profits. Thus, adverse selection helps to explain the observed extraordinary profits.

Finally, the present adverse-selection theory may be compared with that of Joseph E. Stiglitz and Andrew Weiss (1981). Stiglitz and Weiss argue that, if all banks are charging the same interest rate, no one bank will unilaterally deviate and charge a higher interest rate. The explanation is that the only consumer who would borrow at such a high interest rate is one who probably will not repay the debt (i.e., he is undertaking a very risky project). In contrast, if all banks are earning positive economic profits, the Stiglitz-Weiss effect would quicken the banks' tendencies to cut prices. A lower interest rate draws not only more customers but also better customers. Thus, Stiglitz and Weiss predict that interest rates are "upward-sticky" when costs rise and, if anything, interest rates are "downward-quick" in their model.

This is hardly a good description of real-world credit markets. Empirically, interest rates on loans have an asymmetric response to the cost of funds: they are quicker to

move upward in response to increases in the cost of funds than to move downward in response to decreases in the cost of funds. (Marcelle Arak et al. [1983] detected an asymmetric response in movements of the prime rate, and in work in progress, I have found an asymmetric response in many consumer credit markets.)

My adverse-selection theory is a *reverse* Stiglitz-Weiss effect: it creates reluctance to cut interest rates. Thus, it is a completely different and new adverse-selection theory, which may also be useful in explaining other credit markets.

C. Evidence of Consumer Irrationality

The adverse-selection theory of the previous section crucially relies on the assumption that there are consumers who do not intend to borrow but continuously do so. (Many other forms of irrationality would also render consumers insensitive to credit card interest rates.⁴²) In this subsection, I indicate some formal and anecdotal evidence of this and other forms of consumer irrationality in this market.

First, in the author's bank credit card survey, banks were asked for the percentage of their customers who pay off their full outstanding balances (and so are not subject to finance charges) and for the average outstanding balance (see question 8 in Table A1 for the exact text). The responses, summarized in Table 11, reveal that significant finance charges are being paid on the majority of credit card accounts. Despite interest rates exceeding 18 percent per year, typically *three-quarters* of active credit card accounts at major banks are incurring these high finance charges (on balances averaging over \$1,000) at any moment in time.⁴³ The proclivity of consumers to borrow at these

⁴²For example, many consumers may not understand how interest rates work and underestimate the consequences of borrowing.

⁴³The three-quarters figure should not come as a complete surprise. It would certainly have to be in this range, in order for typically 90 percent of a credit card issuer's outstanding balances to be accruing interest. See also footnote 20.

high rates suggests a substantial breakdown in optimizing behavior among credit card holders.⁴⁴ Moreover, the percentages in Table 11 are based on reliable bank data yet contradict the authoritative University of Michigan consumer survey. According to Glenn B. Canner and James T. Fergus (1987 table 3), the 1983 Michigan survey found that 47 percent of all families that use bank or retail cards "nearly always pay in full," 26 percent "sometimes pay in full," and only 27 percent "hardly ever pay in full." Unless this is evidence of a bad consumer survey, it suggests that a sizeable proportion of consumers who borrow on credit cards are unaware of how frequently they do it or, more likely, deny (to themselves and others) that they do it.⁴⁵ In this sense, the data provide indirect empirical confirmation of the presence of consumers who act as though they do not intend to borrow but who continuously do so.

Second, the experience of credit card marketers is that consumers are much more sensitive to increases in the annual fee than to commensurate increases in the interest rate, despite the fact that the majority of cardholders pay significant finance charges. This is behavior that is difficult to rationalize and is again consistent with the presence of consumers who do not intend to borrow but do so anyway.

Third, if advertising campaigns predicated on price are ineffective, it may be wondered what does attract new customers. One notable recent success has been the "Elvis card," which despite a 17.88-percent interest rate (about average) and \$36 annual fee (extremely high for a standard bank card) generated three times the response rate normally experienced by direct mail.⁴⁶

⁴⁴One would expect that optimizing behavior would lead many consumers to (a) shop around for lower-priced credit cards, (b) shift into different modes of borrowing (e.g., home equity loans), or (c) rearrange their intertemporal stream of consumption (i.e., not borrow).

⁴⁵It is possible that consumers who borrow also hold more charge accounts than those who do not borrow; but multiple accounts cannot nearly fully explain the statistical discrepancy.

⁴⁶*Credit Card News*, October 1, 1988.

Fourth, anecdotal evidence suggests that credit card consumers behave significantly different from the ideal of *Homo economicus*. This author's favorite story (heard twice, independently) involves consumers who immerse their credit cards in trays of water and place them in the freezer. The purpose of entombing the card in ice is to precommit to not making impulsive purchases.

Finally, these observations are not specifically confined to the credit card market and, in fact, are consistent with earlier work that has been done in other areas of consumer credit. One of the most surprising such articles is a study by James J. White and Frank W. Munger (1971) which found that recipients of new car loans were extremely insensitive to interest rates. It would be reasonable to expect that consumers are relatively more price sensitive in seeking out automobile loans than credit cards, as the large dollar amount would justify greater search or switch behavior. Nevertheless, White and Munger report that roughly half of the borrowers from the high-cost providers of auto loans in the Michigan locality they studied would have qualified for loans from low-cost providers. Many consumers who apparently could have borrowed at appreciably lower interest rates failed to do so. Moreover, 29 percent of the borrowers from the high-cost providers were specifically aware of at least one nearby lender who charged a lower interest rate, leading White and Munger to conclude that lack of knowledge of lower interest rates was not the principal deterrent to obtaining cheaper loans.

VII. Calculation of a "Competitive" Interest Rate

This article has thus far focused on the discrepancy between the predictions of the competitive model and actual observed behavior in the bank credit card market, while Section VIII will discuss the relative merits of regulating this market. As a bridge between these two strands of thought, this section will briefly inquire as to "competitive" interest rates: what level of interest rates would have been consistent with ordi-

TABLE 12—IMPLIED DIFFERENTIAL BETWEEN "COMPETITIVE" CREDIT CARD INTEREST RATE AND ACTUAL RATE

Year	Number of banks in sample	Adjusted return on assets (percentage)	Implied actual minus "competitive" interest rate (percentage)
1983	6	4.44	3.60
1984	13	4.94	4.16
1985	14	6.23	5.59
1986	15	6.37	5.74
1987	13	5.72	5.02
1988	10	4.72	3.91
Average:	—	5.59	4.88

Notes: Adjusted return on assets is calculated by pooling the banks in Tables 6 and 7 for each year and calculating the arithmetic average of ROA (adjusted). The number of banks in the sample reflects one overlap in the years 1984–1988.

nary returns in the credit card market in the late 1980's?⁴⁷

Suppose an explicit calculation is to be done for the year 1987. Above, I have reported the average adjusted return on assets to be 6.31 percent in the BCCS data (seven banks) and 5.13 percent in the call-report data (seven banks, with one overlap). For the following calculation, I will take 5.72 percent (the arithmetic average for the two samples) to be the actual pretax return on assets. Recall that 1.20 percent has been taken to be the ordinary pretax return on assets in the banking industry. Subtracting and taking "assets" to be equivalent to "outstanding balances," one could conclude that the excess revenues in 1987 were 4.52 percent of outstanding balances. Also recall that, typically, about 90 percent of an issuer's outstanding balances actually accrue interest. This suggests that, if interest rates had been approximately five percent-

age points lower (i.e., 4.52/0.9) in 1987, the top 50 credit card issuers would have still earned the ordinary rate of return in banking. Given that the average annual percentage interest rate for banks in this sample equaled 18.67 percent in 1987, this would imply a "competitive" interest rate of just 13.65 percent. Given that the average one-year Treasury bill yield equaled 7.52 percent in 1987, this also suggests an approximate rule of thumb that, at 1987 levels of annual fees and credit losses and with current usage patterns, the break-even point is roughly approximated by the one-year Treasury bill yield plus slightly more than six percentage points.

Analogous calculations for the period 1983–1988 are displayed in Table 12. Obviously, these calculations are sensitive to the estimate of credit card profitability. However, even using the much more conservative FCA profitability data (see Table 8), one would still find that credit card interest rates in 1987 were three percentage points above the break-even level.

VIII. Implications for Regulation

While this article has argued that the bank credit card market does not mirror the predictions of the model of perfect competition, neither does it necessarily lead to the conclusion that usury ceilings on credit card interest rates should be reestablished. As experience in many industries (e.g., airlines,

⁴⁷Obviously, this is precisely the same question that would have to be asked if the government were to choose to regulate the bank credit card market. Please note that the calculation provided here is meant only to be illustrative and would not be suitable for inclusion in any future statute without further refinement. Note that the calculation assumes, for simplicity, that credit card borrowing is perfectly inelastic in the interest rate (although this may not be a bad approximation of reality). Also note that the calculation assumes a continuous 20-percent return on equity; in fact, one would expect some degree of variation over the business cycle.

trucking, railroads, and banking itself) has demonstrated, it is often difficult to formulate a regulatory rule that unambiguously improves industrial performance. In the industry in question, the particular hazard associated with price controls is the possibility that they would impair the ability of some individuals to obtain credit cards, which are virtual necessities in certain aspects of modern life (such as renting an automobile or ordering by telephone). This section discusses the trade-offs between regulated and unregulated interest rates.

Even if this article does not criticize the recent outcome of the legislative process (i.e., rejecting the reimposition of credit card interest rate ceilings), it does at least argue that the terms of debate have been flawed.⁴⁸ Underpinning the antiregulation argument has been the market description of the credit card business (as presented in the first paragraph of this paper) and the implication that such an industrial structure inexorably leads to the perfectly competitive outcome (with all its desirable efficiency properties). For example, Martha R. Seger, a Governor of the Federal Reserve System, concluded her recent Congressional testimony on the subject by stating:

I would like to reemphasize the Board's conviction that financial markets distribute credit most efficiently and productively when interest rates are determined without artificial restraints, insofar as possible. In the credit card business, the balance of the evidence suggests that reasonably competitive conditions exist, notwithstanding the lack of variation in

finance rates. Furthermore, recent developments have reflected some tendency for credit card rates to decline.⁴⁹

A similar strand of thought is reflected in a recent *Wall Street Journal* editorial: "Credit-card interest almost certainly will come down. It will come down without rate ceilings. Nothing does it like competition."⁵⁰

Such arguments are insufficient. One cannot implicitly rely on the model of perfect competition as the principal defense for laissez-faire, given that the data cast severe doubt on the predictions of zero economic profits and cost-based pricing in this industry.

In order to make a cogent argument against regulation, one must proceed in a much more sophisticated fashion. First, it must be recognized that the behavior of the unregulated credit card market of the 1980's deviates in systematic ways from competitive predictions. The price of credit far exceeds its fundamental marginal cost, and the industry expects this situation to persist for some time. While nonprice competition has so far failed to impair firms' profits seriously, it appears to be steadily escalating, meaning that one can envision a day in the not-too-distant future when economic profits from new customers would be completely competed away via nonprice means. (Banks might still earn significant economic rents from their existing "captive" customers.)

Second, it should equally be recognized that regulation has only a limited potential to improve the outcome. The principal difficulty is that consumers occupy a spectrum of levels of credit-worthiness. Let ρ_n denote the bank's best estimate of the n th con-

⁴⁸ Possible reregulation of credit card interest rates has been the subject of controversy in recent years. In the 1987 Congressional session, no fewer than five bills dealing with credit cards were introduced: Senate Bill S.241 (mandating certain disclosures), S.242 (setting a national ceiling of four percent above the Internal Revenue Service's interest rate), S.616 (disclosure), S.674 (a ceiling of six percent above the Federal Reserve's discount rate), and House Bill H.R.515 (a ceiling eight percent above the one-year Treasury bill rate). In 1987-1988, Congress rejected all proposed bills and amendments setting credit card interest rate ceilings but enacted a mandatory disclosure bill.

⁴⁹ "Credit Card Interest Rates," Hearing before the Subcommittee on Consumer Affairs and Coinage of the Committee on Banking, Finance, and Urban Affairs, House of Representatives, Ninety-Ninth Congress, First Session, on H.R. 1197 and H.R. 3408 (October 29, 1985), Serial No. 99-44, U.S. Government Printing Office, Washington, 1986, page 39; also see *Federal Reserve Bulletin*, March 1986, p. 184.

⁵⁰ *Wall Street Journal*, March 16, 1987, editorial page.

sumer's probability of default and let c denote the marginal cost of lending funds to a consumer (exclusive of default risk). Then, the social optimum has every consumer paying his own, individualized interest rate: consumer n holds a credit card bearing a finance charge of $(\rho_n + c)$.⁵¹ Since conventional usury laws do not set interest rates according to the individual's default risk, ρ_n , they necessarily lead to outcomes that fall short of the optimum. The regulation is typically written: no bank is permitted to charge an interest rate greater than r^* . Under such a regulatory regime, no consumer whose default risk (to an external observer) exceeds $(r^* - c)$ will be serviced. Thus, if r^* is sufficiently low to ameliorate excess profits, it will also generally create deadweight loss by depriving individuals of the opportunity to hold credit cards. Moreover, it has been widely observed that, in an environment with price ceilings, there is a tendency for all firms to charge *exactly* the price ceiling. Hence, one could expect further deviation from the ideal, individualized interest rates: all consumers with default risks less than $(r^* - c)$ may end up paying interest rates equaling r^* .

A decision regarding the advisability of regulation thus involves a comparison of two less-than-ideal alternatives. The case for laissez-faire is strongest when one is only interested in efficiency and when non-interest-rate competition exclusively takes the form of recycling revenues to consumers. It has already been observed that credit card borrowers are highly interest-rate inelastic. Thus, high interest rates may not appreciably reduce the quantity borrowed, and so there may be little efficiency loss arising directly from excessive interest rates. The primary avenue for social loss is then the nonprice competition. However, to the extent that competition takes the form of frequent-flyer miles, cash rebates, or other relatively efficient means of recycling rev-

enues to consumers, there is still no appreciable social loss.

The case for regulation is strongest when one is upset by redistribution away from consumers or when nonprice competition expends substantial resources. I have already observed that high interest rates may be essentially neutral from an efficiency point of view. However, they presumably have a strongly undesirable redistributive effect from the comparatively poor (consumers who borrow on credit cards) to the comparatively rich (owners of bank stock). Moreover, there is a true (and potentially large) deadweight loss when nonprice competition takes the form of advertising.⁵² Some banks' reported noninterest expenses increased significantly from 1983 to 1988 even as the intrinsic cost of servicing accounts declined (e.g., Citibank, which advertises on national television); much of the additional expense probably represents marketing, and some fraction of this constitutes social loss.

IX. Conclusion

Despite the presence of 4,000 competitors, the bank credit card market of the 1980's behaved widely at variance with the predictions of a competitive model in continuous spot-market equilibrium. Interest rates approximated constancy, at levels around 18 percent per year, in the face of wide changes in banks' marginal costs. Profits persistently equaled three or more times the ordinary return on banking equity, with no sign of abatement. A breakdown of the optimizing consumer behavior so basic to the model of perfect competition may be an important element in the story.

The facts of the market are roughly consistent with a model of adverse selection in which many consumers are insensitive to

⁵¹ Either some banks could offer a spectrum of interest rates to different consumers, or banks could each offer just a single interest rate but specialize in consumers of different qualities of credit-worthiness.

⁵² The direct-mail credit card solicitations which I received at the rate of one per week while writing the article inspired this observation. One important, additional aspect of this problem is that the large interest-rate spread (see Section II-B) encourages banks to market cards in an aggressive way that makes them susceptible to fraud losses.

interest-rate differentials because they believe they will pay within the grace period (although they repeatedly fail to do so). This hypothesis is lent some empirical support by the finding that, assurances to the contrary, three-quarters of consumers pay finance charges on their outstanding credit card balances. Given the presence of such consumers, any bank that unilaterally reduced its credit card interest rate would disproportionately draw customers who actually do intend to borrow (i.e., the worst credit risks). Thus, the finance charges remain at high levels and become the main contributors to supranormal profits.

The facts of the market appear to be inconsistent with the predominance of well-informed consumers who are attempting to minimize their borrowing costs. There is no evidence that consumers are generally offered competitive interest rates on bank card balances, nor that most consumers respond to lower interest rates when they are offered.

The empirical findings of this article suggest a broader question: is it that the bank credit card market of the 1980's was uniquely pathological, or can one identify other markets whose structures seem equally conducive to the competitive model but whose empirical outcomes are similarly noncompetitive? This would seem to be a ripe area for further research.

APPENDIX A: THE BANK CREDIT CARD SURVEY

In May 1986, a pilot survey was mailed to 32 banks which were believed to be among the 50 largest bank issuers of credit cards. Five responses were received. The bank credit card survey (BCCS) was formed by using these responses to refine the questions asked. The BCCS was mailed in November 1986 to each of the 50 largest bank issuers of credit cards, as ranked in the *Nilson Report* (Number 371, January 1986), plus five banks ranked numbers 51-60. (The BCCS was not sent to the five banks that had responded to the pilot survey.) Following reminder letters in December 1986 and March 1987, as well as reminder telephone calls, 16 responses to the BCCS were received. Thus, the pilot survey and BCCS together elicited a total of 21 responses from a sample consisting of the following 58 banks:

Associates National Bank
Avco National Bank

BancOhio
Bank of America
Bank of New York
Bank One
Barnett Bank
Beneficial National Bank
Chase Manhattan Bank
Chemical Bank
Citibank
Citizens & Southern National Bank
Comerica Bank
Commerce Bank
Connecticut Bank and Trust Co.
CoreStates Bank of Delaware
Crocker National Bank
European American Bank
First City Bank
First Interstate Bank
First National Bank of Atlanta
First National Bank of Boston
First National Bank of Chicago
First National Bank of Omaha
First Omni Bank
First Tennessee Bank
First Wisconsin National Bank
Harris Trust and Savings Bank
Indiana National Bank
InterFirst Bank
Manufacturers Hanover Trust Co.
Marine Midland Bank
Maryland Bank
MBank
Mellon Bank
Mercantile Trust Co.
Michigan National Bank
National Bank of Detroit
National Westminster Bank
NCNB
Norwest Bank
PNC National Bank
Rainier National Bank
RepublicBank Dallas
Rocky Mountain Bankcard System
Seattle First National Bank
Security Bank and Trust Co.
Security Pacific National Bank
Signet Bank
Southeast Bank
Sovran Bank
State Street Bank and Trust Co.
Sun Bank
United Bank of Denver
United States National Bank
United Virginia Bank
Valley National Bank
Wells Fargo Bank

Several of the listed banks had ceased to exist as credit card issuers by the relevant time period, due to merger of the banks or acquisition of their portfolios. Seventeen responses included full interest rate series for the years 1982-1986 (see Table 2 for sizes), extended

TABLE A1—BANK CREDIT CARD SURVEY

1. Please indicate the interest rate, beginning in 1976 and through the present, on your most widely issued bank credit card:

Name of Card: _____

Year	February	May	August	November
1976	_____	_____	_____	_____
...
1986	_____	_____	_____	_____

Any additional information (for example, a different rate on premium cards, a floating-rate formula which you currently use, etc.):

2. Same as 1, for annual fee.
3. Please briefly describe the method your bank uses to compute bank card finance charges (include grace periods, etc.):
4. Please list charges other than annual fees (e.g., transaction charges, late fees, minimum finance charges, etc.) which your bank has charged between 1976 and the present. Please indicate relevant dollar amounts and dates:
5. Please list all major state and federal regulations (e.g., interest rate ceilings, laws prohibiting annual fees, etc.) which have hampered your operations between January 1976 and the present, indicating effective dates:
6. If your bank has any statement or position paper on credit card regulation, please enclose it with the completed survey.
7. Please indicate your number of total accounts, number of active accounts, total outstanding balances (at June 30 of each year, or another standardized date), annual charge volume, and charge-off rate:

Year	Number of total accounts	Number of active accounts	Outstanding balances	Annual charge volume	Charge-off rate
1976	_____	_____	_____	_____	_____
...
1986	_____	_____	_____	_____	_____

8. Please provide the following information about your cardholders, indicating for each column which of two possible pieces of information you are providing. [If both are available, please provide (A).]

Column 1:

- _____ (A) In an average month, what percent of your active accounts pay off their full outstanding balances (and so are not subject to a finance charge on those balances)?
- _____ (B) What percent of your active accounts pay off their full outstanding balances at least 11 months per year (and so are only subject to a finance charge on their balances at most one month per year)?

Column 2:

- _____ (A) Of your active accounts with outstanding balances, what is the average outstanding balance?
- _____ (B) Of all active accounts, what is the average outstanding balance?

Year	Percent who pay in full	Average outstanding balance
1976	_____	_____
...
1986	_____	_____

9. Please enclose a copy of the credit card application/solicitation(s) your bank uses most.
10. Please indicate which, if any, of the following factors you emphasize in the marketing of your cards.
- _____ Our high credit limit
 - _____ New customers can transfer their existing credit card balances onto our account
 - _____ New customers are waived our first year's annual fee
 - _____ Our interest rate is lower than our competitors'
 - _____ Our annual fee is lower than our competitors'
 - _____ Our card gives "bonus dollars" with each dollar charged, for discounts on merchandise
 - _____ Pre-approved credit card applications
 - _____ Free airline insurance
 - _____ Other freebies—list them:
 - _____ Other factors—list them:
11. Feel free to include any additional comments, either below or on separate sheets of paper.

TABLE A2—FOLLOW-UP BANK CREDIT CARD SURVEY (AND FOLLOW-UP SURVEY II)

1. 1987 (1988) updates of Questions 1 and 2 from Bank Credit Card Survey.
2. 1987 (1988) updates of Question 7 from Bank Credit Card Survey.
3. 1987 (1988) updates of Question 8 from Bank Credit Card Survey.
4. Please enter all available dollar figures for your bank's *credit card business only*. [Question 4 was patterned after the Federal Reserve System's *Functional Cost Analysis*. A xerox copy of p. 38 of the 1986 report was enclosed.]

	1984	...	1987 (1988)
1. Average total outstanding balances:	\$ _____	...	\$ _____
Income:			
2. Finance charge interest and customer fees (including annual fee):	\$ _____	...	\$ _____
3. Merchant discount, interchange fees, and other income:	\$ _____	...	\$ _____
4. Total income (2 + 3):	\$ _____	...	\$ _____
Operating expenses:			
5. Marketing and advertising:	\$ _____	...	\$ _____
6. Enhancements and affinity program expenses:	\$ _____	...	\$ _____
7. All other expenses (including salaries, fringe benefits, data services, processing, franchise fees; excluding items below):	\$ _____	...	\$ _____
8. Total operating expenses (5 + 6 + 7):	\$ _____	...	\$ _____
Earnings:			
9. Net earnings before losses (4 - 8):	\$ _____	...	\$ _____
10. Net credit losses:	\$ _____	...	\$ _____
11. Net fraud losses:	\$ _____	...	\$ _____
12. Net earnings (9 - 10 - 11):	\$ _____	...	\$ _____
Memoranda:			
13. Cost of funds:	\$ _____	...	\$ _____
14. Net earnings (pretax) after cost of funds (12 - 13):	\$ _____	...	\$ _____

through 1987 by contemporaneous telephone calls. Respondents were promised anonymity.

The follow-up bank credit card survey was mailed to the 21 initial respondents in January 1988, requesting both 1987 updates of data that the original survey had elicited and direct reports of credit card profits. Follow-up survey II was mailed to the 21 respondents in February and July 1989, requesting both 1988 updates of data that the original survey had elicited and direct reports of credit card profits. Following reminder letters, 11 responses were received, seven of which contained data on profits for 1984–1987 (see Table 2 for sizes) and five also for 1988. The profit reports of Bank F and all 1988 profit reports were completed by banks after the working-paper precursor of this article was made available to the banks. Respondents were again promised anonymity. The BCCS and follow-up BCCS are reprinted in Tables A1 and A2 in condensed form.

APPENDIX B: PROFITABILITY CALCULATIONS

Bank Credit Card Survey Data

COST OF FUNDS is defined by taking the one-year Treasury-bill yield plus 0.75 percent, averaged over the calendar year, and multiplying by 0.94. The Treasury-bill yield is taken from the *Federal Reserve Bulletin*, April 1990, table 1.35, line 21 (and previous issues). The number 0.75 represents the spread between yields on Treasury securities and yields on credit-card-backed securities. The number 0.94 represents 1 minus the banking system's capital requirement of 6 percent.

The numbers reported in Table 6 were constructed as follows (see also Table A2):

$$\text{ROA (reported)} = \text{BCCS Line 14} / \text{BCCS Line 1}$$

$$\begin{aligned} \text{ROA (adjusted)} = & (\text{BCCS Line 14} + \text{BCCS Line 13} \\ & - \text{COST OF FUNDS} \times \text{BCCS} \\ & \text{Line 1}) / \text{BCCS Line 1} \end{aligned}$$

$$\text{ROE (adjusted)} = \text{ROA (adjusted)} / 0.06.$$

Call Report Data for Credit Card Banks

The calculations reported in Table 7 are based on the quarterly consolidated reports of condition and income ("call reports") which "credit card banks" filed with the FDIC. Included in the sample were all commercial banks that met both of the following criteria:

- 1) credit card balances constituted at least 75 percent of the bank's total assets (so that the bank's profits are a good proxy for profits attributable to the credit card business);
- 2) the bank's balance sheet was not seriously marred by credit card securitizations or portfolio acquisitions.

For example, Maryland Bank was excluded from the sample in 1988, because that bank's credit card balances averaged \$3.1 billion in that year, while only \$1.7 billion appeared on the bank's Report of Condition (the remainder having been securitized). Typically, for banks in Table 7, credit card balances constituted 97 percent or more of total assets.

In the description immediately below, the December 31, 1987 call report for Citibank (South Dakota), N.A., is used to standardize line numbers. The following data were extracted from credit card banks' call reports:

AVERAGE TOTAL ASSETS = Schedule RC-K, line 9 [Total Assets] – Schedule RC, line 10 [Intangible Assets] (this calculation is performed for each of the March 31, June 30, September 30, and December 31 reports; I work with the arithmetic average of the four numbers);

TOTAL EQUITY PREVIOUS YEAR = Schedule RI-A, line 3 [Amended Balance End of Previous Calendar Year];

INCOME BEFORE TAXES = Schedule RI, line 8 [Income Before Income Taxes and Extraordinary Items];

PROVISION FOR LOAN LOSS = Schedule RI, line 4A [Provision for Loan and Lease Losses];

NET CHARGEOFFS = Schedule RI-B, line 9, column A [Total Charge-Offs] – Schedule RI-B, line 9, column B [Total Recoveries];

INTEREST EXPENSE = Schedule RI, line 2F [Total Interest Expense];

COST OF FUNDS = as in first paragraph of this appendix;

AMORTIZATION EXPENSE OF PREMIA = Schedule RI-E, line 2A [Amortization Expense of Intangible Assets].

The numbers reported in Table 7 were then constructed as follows:

ROA (reported) = (INCOME BEFORE TAXES + PROVISION FOR LOAN LOSS – NET CHARGEOFFS) / AVERAGE TOTAL ASSETS;

ROE (actual cap) = (INCOME BEFORE TAXES + PROVISION FOR LOAN LOSS – NET CHARGEOFFS) / TOTAL EQUITY PREVIOUS YEAR;

ROA (adjusted) = (INCOME BEFORE TAXES + PROVISION FOR LOAN LOSS – NET CHARGEOFFS + INTEREST EXPENSE – COST OF FUNDS × AVERAGE TOTAL ASSETS + AMORTIZATION EXPENSE OF PREMIA) / AVERAGE TOTAL ASSETS;

ROE (adjusted) = ROA (adjusted) / 0.06.

Prospectus Data

The calculations reported in Section III-D are based on information contained in prospectuses and registration statements filed with the SEC in connection with all public credit card securitizations by commercial banks from 1987 to early 1990. The following is a complete list of the banks and the prospectuses used.

- 1) BancOhio (National City Corporation): National City Credit Card Trust 1990-A, registration statement dated January 2, 1990, pp. 17, 23;
- 2) Bank of America: California Credit Card Trust 1987-A, prospectus dated February 25, 1987, pp. 10, 14; California Credit Card Trust 1987-B, prospectus dated June 19, 1987, pp. 11, 14;
- 3) Chemical Bank: Chemical Bank Credit Card Trust 1988-A, prospectus dated August 16, 1988, pp. 14, 15; Chemical Bank Credit Card Trust 1989-A, prospectus dated October 30, 1989, pp. 16, 19;
- 4) Citibank (South Dakota)/Citibank (Nevada): Money Market Credit Card Trust 1989-1, prospectus dated January 25, 1990, pp. 21, 23;
- 5) Colonial National Bank U.S.A.: Colonial Credit Card Trust 1988-A, preliminary prospectus dated March 23, 1988, pp. 18, 23;
- 6) First National Bank of Chicago/FCC National Bank: First Chicago CARDS Trust 1987-1, prospectus dated September 29, 1987, pp. 13, 15; First Chicago Master Trust, registration statement dated November 16, 1989, pp. 16, 17;
- 7) Lomas Bank U.S.A.: Lomas Credit Card Trust 1989-A, registration statement dated July 3, 1989, pp. 17, 24;
- 8) Manufacturers Hanover Trust Company: MHARCCS Trust 1988-1, prospectus dated June 21, 1988, pp. 17, 18 (1988 only through March 31);
- 9) Maryland Bank, N.A.: MBNA Credit Card Trust 1988-B, prospectus dated September 9, 1988, pp. 16, 21; MBNA Credit Card Trust 1989-B, registration statement dated November 8, 1989, pp. 16, 20;
- 10) RepublicBank Delaware: securitization of January 16, 1987, as summarized in *Standard & Poor's Asset-Backed Securitization CreditReview*, March 16, 1987, pp. 21, 22;
- 11) Southeast Bank: Southeast Bank Credit Card Trust 1990-A, registration statement dated January 29, 1990, pp. 17, 22.

Premia Paid for Credit Card Portfolios

Table 9, the list of premia paid for credit card portfolios, reflects manual and computerized searches of national newspaper indexes over the period January 1984–April 1990. In order to be included, a transaction was required to meet all of the following criteria:

- 1) the transaction was reported in the *Wall Street Journal*, *The New York Times*, *The American Banker*, or the Kidder, Peabody & Co. report (Kristina E. Andersson and Alison A. Deans, 1989);
- 2) the exact premium, the parties to the transaction, the approximate date of the transaction, and the approximate size of the portfolio were reported;
- 3) the transaction was essentially an unbundled sale of credit card accounts and nothing else.

In the event of conflicting reports, the conflict was resolved using the best available information.

Externalities and Growth Accounting

By JESS BENHABIB AND BOYAN JOVANOVIĆ*

This paper tackles two puzzles: the high empirical elasticity of aggregate output with respect to the measured capital input and the seemingly high variability of growth rates over countries in the medium run. We find that one need not invoke increasing returns or externalities to capital to explain these two puzzles. Rather, they are consistent with a constant-returns-to-scale aggregate production function, so long as the exogenous Solow residual process has enough persistence in it. In our model, causality runs exclusively from knowledge to capital, and therefore the apparent absence of an external effect to the capital input says nothing about the importance of spillovers in the creation of knowledge. (JEL 110)

This paper addresses the question of how to explain the variation in the levels and rates of growth of output across countries. It focuses in particular on the question of whether or not this cross-country variation offers support for the suggestion that there are aggregate increasing returns to capital and labor caused either by external effects associated with capital investment or by a secular increase in the variety of intermediate inputs. By looking again at the evidence considered by Paul Romer (1987) and Lawrence Christiano (1987), we show that, under plausible assumptions about the behavior of the economy, there is no support for the assertion that capital-related externalities are present. We show instead that the variation in countries' growth rates is consistent with each country having the same constant-returns-to-scale production function and with a stochastic process for technological change that is the same across different countries but starts from different initial positions.

A. The Issues

Two issues are at hand. The first concerns the prediction of Robert Solow's (1957) model that the elasticity of output with respect to capital should equal capital's share in output, which is roughly one-third. Yet when one looks at data over longer periods of time and in several different countries, as Romer (1987) has, one finds an elasticity that is closer to unity. There are three extensions of Solow's model that can generate this. One is to make the identifying assumption that Romer makes, at least implicitly, that the fundamental exogenous variation is in the rate of savings and investment. In this case, one must change the elasticity of output with respect to capital by invoking capital-related external effects or increasing returns stemming from input variety. The second possibility is to make the identifying assumption that Christiano (1987) makes and that we discuss in Section IV, namely that the exogenous variation across countries is in the underlying exogenous process of technical change. The third alternative, suggested here, is to assume that the fundamental stochastic process for technology is the same but that in the sample the realized paths differ across countries. In this case, something like Christiano's explanation can be constructed (and no capital externalities are needed), but this can be done without invoking his unattractive "fixed effects" as-

*Professors of Economics, New York University, 269 Mercer Street, New York, NY 10003. We thank The C. V. Starr Center for Applied Economics for financial and technical assistance, Francesco Goletti and Ray Atje for research assistance, and Bob Barro, Will Baumol, Larry Christiano, Stan Fischer, Zvi Griliches, Ned Nadiri, Ariel Pakes, and Paul Romer for helpful comments. An earlier version was given at an NBER growth conference in Cambridge, Massachusetts, in October 1989.

sumption that there are permanent, exogenous differences in the technology faced by different countries. Rather, the difference across countries lies in the initial conditions and implicitly in the sequence of historical accidents that lead to those conditions. We deal with this first issue in Section IV.

The second issue is whether (our version of) Solow's model can be reconciled with the seemingly large variation in countries' growth rates since World War II. We shall argue that this variation is roughly consistent with Solow's model. Part of the new evidence that we bring to bear on this assertion is the finding that, for the population of countries as a whole, the time-series variation in output growth in a representative country is consistent with the cross-country variation in output growth measured over 25 years. This bears on the question of the inherent differences, if any, that must be invoked to explain the disparate behavior of the different countries. We deal with this second issue in Section III.

B. Capital and Knowledge

There seems, on first consideration, to be little reason to expect a firm's investment in capital to have substantial beneficial spillover effects in reducing production costs of other firms. However, if firms with more capital also have more productive knowledge and if this knowledge spreads to other firms, then unless one can somehow measure knowledge and control for it, an increase in the capital stock of one firm will appear to lower the production costs of other firms. In the same vein, if the economy's capital stock is positively related to the availability of specialized intermediate inputs and if these inputs are not measured, the growth of capital will appear to increase aggregate output by more than its private marginal product.

In his pioneering article, Romer (1987) offers two separate models each of which can generate a capital elasticity of output larger than one-third. Within the context of his first model, he argues that a large positive externality in capital formation is

needed to explain the strong positive association in aggregate data (over countries and over epochs) between the "Solow residual" and the growth of the capital stock. Moreover, the size of his externality estimate is staggering: the social marginal product of capital, suggests Romer, is perhaps twice or even three times its private marginal product, and by implication, the equilibrium level of investment falls far short of its socially optimal level.¹

Romer's second model introduces knowledge explicitly in the form of ideas for intermediate goods. In its implications for comovements between aggregate output, capital, and labor, this model is observationally equivalent to a version of his first model, as is evident in his equation 11. This model need not have any *direct* spillovers of knowledge to yield aggregate increasing returns, although in later versions Romer introduces direct spillovers in the research sector. The "externality" that the final goods sector enjoys is, as Romer points out, a pecuniary one, and a divergence between equilibrium and social optimum could arise solely because of the monopoly power introduced into the intermediate-goods sector so as to provide incentives for inventions.

Romer's two models have a common feature: growth in capital *causes* a growth in knowledge or a growth in the availability of specialized inputs, or both.² Evidence of direct spillovers of knowledge then constitutes support for Romer's first model. On the other hand, evidence that *pecuniary* spillovers are present (and that such spillovers increase with the capital stock) would provide support for the second model, so long as some increasing returns (as inputs *and* variety vary) are also present. Un-

¹Christiano (1987) challenges these conclusions, claiming that a balanced-path outcome for the Solow model is consistent with the data and that no capital externality is required. Indeed, in the deterministic case, along the balanced-growth path, the externality cannot be identified. Martin N. Baily (1987) and others have made the same point. We return to Christiano's argument in Section IV.

²See especially Romer's reference to evidence from Jacob Schmookler (1966) to the effect that in various industries patenting tends to *follow* investment.

fortunately, the available evidence often mixes the two types of externality (pecuniary and nonpecuniary) so that their relative (as well as absolute, it turns out) importance is hard to pin down.

We begin with the assumption, implicit in Romer's first model, that an increase in a firm's capital stock causes the firm's productive knowledge to go up in the same proportion, so that we can use estimates from micro data on externalities in R&D as an estimate of the size of the capital externality. If direct spillovers to R&D do exist, they are likely to be largest among firms in the same industry, since those firms are likely to be using similar technologies. The largest *intraindustry* spillover estimates were obtained by Jeffrey Bernstein and Ishaq M. Nadiri (1989), who find that, in four industries, the social returns to intraindustry spillovers of R&D ranged from 30 percent to 123 percent of the private returns to R&D.³ Such large estimates are, however, exceptions: in a summary of the literature

on the elasticity of output with respect to the R&D input, Zvi Griliches (1988 p. 15) reports that "while the presence of spillovers would make one expect the industry-level coefficients to be higher than those estimated at the firm level, the econometric estimates do not show this in any convincing fashion."⁴ If aggregating up to the industry level makes little difference to the estimates of the R&D coefficient, it would be quite surprising if aggregating to the whole economy would produce a large upward revision (specifically, a tripling) of the R&D coefficient. However, this is exactly what Romer's first argument implies, and the micro data do not seem to support it.

The micro evidence does not seem to favor Romer's second argument either. Frederick M. Scherer (1982) finds that productivity growth in an industry is strongly correlated with the extent to which it purchases R&D-embodied products. Additionally, a wealth of evidence points to sustained cost reductions in a whole range of intermediate-inputs services. It is beyond dispute, therefore, that final-goods producers have benefitted from sustained improve-

³Edwin Mansfield et al. (1977) also find large spillovers for a select group of innovations, but since these were all *successful* innovations, their sample does not accurately represent the outcome of investments in R&D. On the other hand, while the absolute value of the private and social rates of return is clearly biased upward in their sample, their *relative* magnitudes are perhaps not biased. Among their 18 innovations, the social rate of return averaged 77 percent, while that of the private rate averaged 33 percent. These results do support Romer's claim that the social returns might exceed the private rate by a factor of more than two. Bernstein and Nadiri's results must also be viewed with caution, because they are based on a deterministic model, and simultaneity biases are likely to be present because of omitted time effects and unobservable industry effects. In essence, they evaluate the spillover from the partial correlation between a firm's investment in physical capital and R&D on the one hand and the industry investment in R&D on the other. These variables will usually be positively correlated, because they both will respond to industry shocks, time effects, and so on, and this response will cause an upward bias on any estimate of R&D spillovers that relies on this partial correlation. Similarly, Adam Jaffe's (1986) finding that there were significant spillovers in a cross section is questionable on grounds that his assumption (on p. 992) about an absence of correlation between his instrumental variables and the unobserved "technological opportunity" parameter that each firm faces is unlikely to be met.

⁴Ariel Pakes and Mark Schankerman (1984b) find a much stronger correlation between industry-wide R&D and lagged industry growth than they do between firm R&D and firm growth. However, they interpret the causality as running from industry growth to R&D, in the spirit of Schmookler's argument that the incentive to do R&D increases as market size grows. It seems crucial, at the industry level, to impose assumptions that allow one to distinguish shifts in product-demand from shifts in technological opportunity. A different, and more questionable, source of evidence on spillovers is the rate at which the economic value of private knowledge decays. The faster a piece of knowledge spills over to other firms, the faster, presumably, is the loss of economic rent that the firm can extract from that piece of knowledge. Pakes and Schankerman (1984a) find that knowledge depreciates much faster than physical capital, although they do not interpret this as implying a high spillover rate for knowledge. Unfortunately, as Griliches (1979) points out, the value of private knowledge may decay not just because it "leaks" to other firms but also because it is superseded by new knowledge generated by other firms. In other words, the economic value of knowledge would depreciate even in a world with no spillovers, and its depreciation rate is thus an unreliable indicator of the extent and speed of spillovers.

ments in input quality. This does not mean however, that there are increasing returns in the aggregate. In fact, we know of no evidence that (a) aggregate returns to measured inputs *and* variety increase or (b) the provision of variety is fueled by a larger stock of capital.

In short, the micro data are so far not conclusive on Romer's hypotheses. Our aim here is to show that *aggregate* data are consistent with a view that neither direct nor pecuniary spillovers are fueled by physical capital. In doing this, we leave open the possibility that there are increasing returns due to something else—human capital, perhaps.

C. Our Argument

In our model, causality runs entirely from knowledge to capital. Knowledge evolves exogenously; we do not estimate its external effects, and indeed, under our assumption about causality, micro evidence in spillovers of knowledge says *nothing* about spillovers to the capital input. The popular view that some capital investment is needed for the implementation of new ideas favors our causality assumption, since it is natural (as in Andrei Shleifer [1986], for instance) to imagine that new ideas precede the installation of the capital equipment needed to implement them. Moreover, at the level of the individual firm at least, micro data indicate that R&D Granger-causes investment, but that investment does not Granger-cause R&D (Saul Lach and Mark Schankerman, 1989).

While it reverses the assumption about causality between capital and knowledge, our model still admits the possibility of an externality to the capital input and is in fact almost the same as Romer's. Our conclusions, however, are quite different: we examine a variety of bodies of data and find no evidence to support the hypothesis that there are beneficial spillovers arising from the capital input. The reason why our conclusions differ from Romer's is roughly as follows. Romer faces simultaneity problems when he estimates a production function in which capital and labor are endogenous and

correlated with the disturbance to the production function. One source of disturbances to the production function is the business cycle, and Romer tries to remove it by filtering out the high frequencies with long-run averages. He further recognizes that, even in the long-run data, low-frequency movements in technology might create a correlation between the inputs and the production-function disturbance, but he argues⁵ that the extent of this correlation could not plausibly be so large as to reverse his conclusions. This, however, is where we disagree with his argument. We make explicit assumptions about the way in which the capital and labor inputs evolve in response to changes in the state of technology. These assumptions enable us to calculate the correlation between the inputs and the disturbance. We find that, even in the long-run data, this correlation is plausibly high enough to explain the high empirical elasticity of output with respect to the capital input. Moreover, the positive association between knowledge shocks and capital investments also seems to explain most of the variance in countries' growth rates in the postwar period. No externalities or increasing returns are needed.

Section I presents our model, which consists of five structural equations. In Section II, we present maximum-likelihood and least-squares estimates for the model using postwar quarterly and annual U.S. data and find no evidence of an externality. In Section III, we then discuss some of the model's implications about the convergence of GNP among different countries, and interpret the apparent empirical validity of "Gibrat's Law" in the behavior of countries' GNP series over extended periods. In Section IV, we reinterpret Romer's regression results (which use data on growth of inputs and output over long epochs) in terms of the simultaneity biases that we calculate, and we conclude that even those data offer no

⁵Especially on p. 194 with reference to evidence on the persistence of cross-country differentials in growth rates.

evidence for the conjectured positive externality to the capital input.

After the empirical evidence discussed in Sections II–IV, Section V presents two models that give rise to the structural equations first introduced in Section I. The first is a stochastic Diamond type of overlapping-generations model, the second a Brock-Mirman type of infinite-horizon model. The sixth and final section offers some concluding remarks.

I. The Augmented Solow Model

The representative firm produces output Y_t with hired inputs K_t and L_t , taking as given the economy-wide capital stock \bar{K}_t per firm and the state of knowledge Z_t . The production function is

$$(1) \quad Y_t = K_t^\alpha L_t^{1-\alpha} \bar{K}_t^\theta Z_t.$$

In the first version of Romer's model, the parameter θ measures the external effect of capital, an effect that the firm ignores when making its decisions. In the second version, θ represents increasing returns in the variety of intermediate inputs whose quality is (in an auxiliary equation) linked to the economy-wide capital stock. Since all firms are the same, $K_t = \bar{K}_t$. Letting lowercase symbols denote logarithms, (1) reads

$$(2) \quad y_t = (\alpha + \theta)k_t + (1 - \alpha)l_t + z_t.$$

When $\alpha + \theta$ is unity, this equation is the same as Romer's equation 11. If the firm is a price-taker in its product and factor markets, α is capital's share in output, and $1 - \alpha$ is labor's share. This is Romer's reformulation of Solow's model.⁶

To this, we now add assumptions about how knowledge grows and about how the equilibrium k_t and l_t evolve. Knowledge evolves exogenously, as follows:

$$(3) \quad z_{t+1} = \mu + \rho z_t + \omega_t \quad |\rho| \leq 1$$

$$(4) \quad \omega_t = \varepsilon_t + \lambda_1 \varepsilon_{t-1} + \lambda_2 \varepsilon_{t-2}.$$

⁶At least a part of this model is in Griliches (1979 p. 102); Griliches there attributes it to an unpublished note by Yehuda Grunfeld and David Levhari.

Thus, the z_t process is an ARMA(1,2). Three features of (3) and (4) deserve mention. First, μ is the rate of exogenous technical change; one expects it to be positive, since some knowledge comes for free from abroad, and in addition, some knowledge is generated for free domestically as a by-product of everyday economic activity. At any rate, the economy's long-run growth rate in GNP per capita will be $\mu(1 - \alpha)$ if ρ is unity and 0 if ρ is less than 1. On these grounds, we expect ρ to be roughly equal to unity. Second, the parameter ρ , or rather $1 - \rho$, measures the rate at which knowledge depreciates.⁷ From the work on business cycles by Edward C. Prescott and his coworkers (e.g., Prescott, 1986), we expect ρ to be about 0.99 in the quarterly U.S. data and 0.96 in the annual data. An important omission here is a purely transitory component to z . Its inclusion would almost certainly raise the estimates of ρ that we present in the next section and would work in our favor. In other words, the inclusion of transitory monetary and other policy effects on the measured Solow residual and even of errors in measuring z_t would, as will become clear below, help rather than hurt our case, which hinges on ρ being close to 1. Third, the MA(2) specification for ω_t was entirely arbitrary; it took two moving-average terms to remove the autocorrelation from the residuals in the quarterly U.S. data.

Next we specify the behavior of the capital and labor inputs. In Section VI, we shall present two separate micro models⁸ that imply the following equation as governing competitive equilibrium allocations:

$$(5) \quad k_{t+1} = \gamma + y_t$$

where γ is a constant.⁹ For some of the

⁷Because it is superseded by other knowledge. Actually, it is not knowledge but rather its economic value that depreciates.

⁸One of these is in many respects similar to the model that Edward Prescott (1986) proposes for business-cycle analysis.

⁹Equation (5) is an exact specification for the infinite-horizon representative-agent model with logarithmic utility, Cobb-Douglas production and 100-percent depreciation of capital. The details are in Section V.

results in Sections II and IV, we also assume that

- (6) l_t is a stochastic process
independent of z_t .

This assumption, which is also given a micro justification in Section VI, is not used in Section III, however, where we interpret long-run growth differentials in countries' growth experience.

Equations (2)–(5) and assumption (6) make up the model. In sum, it is Romer's model with the added assumptions of exogenous knowledge and endogenous capital and labor. The next three sections describe how we have estimated its parameters. Section II uses postwar U.S. data, Section III uses Alan Heston and Robert Summers's (1984) data, and Section IV uses the longer-run data that Romer compiled from Angus Maddison (1982) and elsewhere. None of these bodies of data supports the hypothesis that θ is positive.

II. Estimates From Postwar U.S. Data

We begin our empirical inquiry by looking at the postwar U.S. data. The reader will not be surprised to learn these data offer no support for a positive θ , since (a) Romer himself did not cite these data as supportive of capital externalities, (b) Prescott (1986) has, with some success, used a model quite similar to ours but with θ set equal to 0 to fit detrended postwar U.S. data, and (c) the short-run data are notorious in that output fluctuations are explained almost entirely by variations in

hours worked and hardly at all by the measured capital input.

A problem presented by the capital input is that it is likely to be poorly measured, at least at high frequencies, because of variation in its utilization rate. Our estimation procedure in this section begins by treating k_t as unobservable. This assumption underlies the calculation of the estimates in the first four tables. Tables 5–8, on the other hand, do use capital data.

Substitution of (5) into (2) yields

$$(7) \quad y_t = (\alpha + \theta)\gamma + (\alpha + \theta)y_{t-1} \\ + (1 - \alpha)l_t + z_t.$$

This is the equation that formed the basis for the estimates reported in the first two tables, which used data on $\log(\text{GNP})$ for y_t and $\log(\text{hours worked})$ for l_t . The data are *not* detrended. We present two sets of estimates. Table 1 reports the unconstrained maximum-likelihood estimates¹⁰ for the annual and the quarterly data separately. Table 2 reports estimates for the remaining parameters when α is constrained to equal $\frac{1}{3}$ (i.e., capital's postwar share in income).

Several points are noteworthy. For the quarterly data, the unconstrained estimates are virtually the same as the constrained estimates, and the likelihood ratio does not significantly differ from one. The estimate of ρ is about the same as that of Prescott (1986 p. 15). The estimate of θ is close to 0 and does not differ significantly from 0. When α is freed up, its estimate does not

¹⁰The likelihood was derived as follows. Multiplying (7) through by ρ , lagging one period and subtracting the result from (7) yields

$$y_t - \rho y_{t-1} = C + (\alpha + \theta)(y_{t-1} - \rho y_{t-2}) \\ + (1 - \alpha)(l_t - \rho l_{t-1}) + \omega_t$$

where $C = (1 - \rho)[(\alpha + \theta)\gamma + \mu]$. The ε_t are assumed to be normally distributed. Since ω contains two moving-average terms, we used the Box-Jenkins procedure, setting the two presample error terms to their zero means. For y , we use $\log(\text{GNP})$ in 1982 dollars; for l , we use \log of total hours worked; and for k , we use the \log of total (private fixed plus government) capital, all for the period 1947–1985, or 1986.

However, for a model with less than 100-percent depreciation and general functional forms, the qualitative features of this relationship, that is the positive covariance of k_{t+1} with k_t as well as z_t , which are the critical elements driving our results in the following section, will be preserved under very reasonable assumptions. This issue is explicitly discussed in Section V (especially see Lemma 1 and the surrounding discussion). Moreover, in Section II we shall also present the estimates for the model's parameters when the evolution of the capital stock obeys $K_{t+1} = sY_t + (1 - \delta)K_t$ instead of (5) (see Tables 3 and 4). We shall also present estimates in Tables 5–8 that use capital data and hence bypass (5) and (5').

TABLE 1—UNCONSTRAINED MAXIMUM-LIKELIHOOD ESTIMATES, BASED ON (5)

Data	Parameter	Estimate	SE	<i>t</i>	<i>P</i>
Yearly ^a	ρ	0.92	0.02	38.84	0.000

	<i>C</i>	-0.02	0.03	-0.54	0.585
	λ_1	-0.16	0.04	-3.81	0.000
	λ_2	-0.18	0.04	4.39	0.000
	σ_e^2	0.00007			

Note: The estimates we constrained in that $\alpha = \frac{1}{3}$.

^aLog likelihood = 94.09 (37 observations, 32 degrees of freedom).

^bLog likelihood = 547.82 (166 observations, 161 degrees of freedom).

differ significantly from $\frac{1}{3}$. All in all, then, the model does pretty well with the quarterly data.

Such is not the case with the annual data. The unconstrained estimate of α is negative, but not significant; and, θ is positive, but small and nonsignificant. Thus, the social marginal product of capital appears to be low in these data. This is especially clear in the first panel of Table 2 in which, when α is constrained to $\frac{1}{3}$, θ is large but negative and highly significant. The likelihood-ratio

test resoundingly rejects the restriction that $\alpha \equiv \frac{1}{3}$. These results with annual data are quite similar to the regression results that Romer reports in line 2 of his table 2; in this regression, he allows (as we do) for exogenous technical change and measures (as we do) the labor input by hours worked.

An important source of downward bias on θ deserves mention, however. While our specification (4) does allow for transitory components in y , there may nevertheless be measurement error in y that will cause the

coefficient of lagged y in (7), namely $\alpha + \theta$, to be underestimated because of errors-in-variables bias. In Table 2, this will cause θ to be underestimated, while in Table 1, where α is freed, both α and θ may be underestimated. Put differently, measurement error in y will lead to a spurious negative dependence between the quasi-first differences in footnote 10. Such a negative bias could hide a positive θ .

A second set of problems arises because it takes time to build capital, and it also takes time for the external benefits of capital accumulation to be felt. That is, it is possible not only that there are significant building-time delays, but that externalities affect output with a lag. To test for the presence of such delays, we considered a production function $Y_t = K_{t-p}^\alpha L_t^{1-\alpha} K_{t-s} Z_t$, where p and s represent lags (presumably, $0 \leq p \leq s$). We derived the corresponding reduced form [the analogue of (7)] for the infinite-horizon representative-agent model where y on the right-hand side appeared with lags s and p . We estimated this model using quarterly data for various values of s and p and found that the best fits, in terms of likelihood, were for $s = p = 0$. For all values that we checked for $s > 0$ (up to $s = 12$) and $p = 0$, the externality coefficient θ was 0, and for values $s \equiv p > 0$, it tended to be negative.

A third set of problems surround our assumption in equation (5) about the way in which capital evolves. Distinct from the issues discussed above concerning the length of time that it takes to build capital, there is the issue of how long capital remains productive after it has been built; that is, how fast it depreciates. If y_t is measured by GNP, as we have done, then equation (5) implies that there is 100-percent depreciation. On the other hand, if Y_t is interpreted as wealth, then we have not measured wealth correctly; instead we should have used net national product plus the entire existing capital stock. However, then it is not clear that (1) is the correct production function, and empirical implementation demands an accurate K_t series. For these reasons, we did not pursue this route. Instead we took the following alternative. In

place of equation (5) (for which a micro-based justification exists [see Section III]), we posited the ad hoc Solow-type constant-savings rule out of income, along with the conventional assumption that capital depreciates at a constant rate δ . This leads to the following equation for the growth of capital:

$$(5') \quad K_{t+1} = sY_t + (1 - \delta)K_t.$$

Tables 3 and 4 report respectively the unconstrained and constrained (by $\alpha = \frac{1}{3}$) estimates of the parameters when (5') is used in place of (5). Only annual data are used, since we did not have a long enough quarterly time series at the depreciation rates that are commonly used.¹¹ The first set of estimates in Tables 3 and 4 sets δ at 10 percent; the second sets it at 8 percent. The parameter C is the same as before (see footnote 10) with $\gamma = \ln s$. Further detail is in Appendix 3.

All of the estimates imply a significantly *negative* marginal social product of capital, at magnitudes that are simply incredible. Evidently, (5') lends even less support than does (5) to the idea that there are positive externalities to the capital input, or to the notion that in the aggregate production function returns to scale are increasing. The first four tables relied on (5) or (5') to eliminate the capital input from the production function. The next four tables present estimates that use the capital series directly. In Table 5, the low estimate of α is probably due to the high short-run elasticity of output with respect to labor, which is higher than labor's share, $1 - \alpha$. Given that α is set at 0, θ becomes the output elasticity with respect to capital. Thus, Table 5 cannot really be interpreted as supporting the hypothesis that θ is positive. The estimates in Table 6 are more favorable to the hypothesis; α is now constrained to equal $\frac{1}{3}$, yet θ is

¹¹We did experiment with postwar quarterly data, using a 10-year weighted average of past Y_t 's to construct the capital stock. The estimate of θ (with α not constrained) was -1.52 and significantly different from zero. Thus, when (5') is used in place of (5), the annual and quarterly data both yield estimates of θ far below these in Table 1.

Notes: $R^2 = 0.98$, $\bar{R}^2 = 0.98$, residual SS = 0.04, SE of estimate = 0.03, total SS = 4.14, $F_{[3,34]} = 1,420.61$, $P = 0.00$, Durbin-Watson statistic = 0.60 (37 observations, 34 degrees of freedom).

TABLE 8—OLS ESTIMATES USING ANNUAL CAPITAL DATA: GROWTH RATES

Parameter	Coefficient	SE	<i>t</i>	<i>P</i>
<i>C</i>	0.02	0.02	1.26	0.215
$1 - \alpha$	1.01	0.16	6.13	0.000
$\alpha + \theta$	-0.35	0.75	-0.47	0.641

Notes: $R^2 = 0.54$, $\bar{R}^2 = 0.51$, residual SS = 0.01, SE of estimate = 0.01, total SS = 0.02, $F_{[3,33]} = 19.79$, $P = 0.00$, Durbin-Watson statistic = 0.78 (36 observations, 33 degrees of freedom).

still positive and significant. This is the only solid piece of evidence in favor of Romer's hypothesis that we can find in the postwar data. At the same time, the estimate of ρ is surprisingly low. Tables 7 and 8 present ordinary least-squares (OLS) estimates of the aggregate production function. If ρ is close to 1, and if (5) is appropriate for annual (as opposed to quarterly) data, then according to the model in equations (2)–(5) and assumption (6) the OLS estimates of the coefficients in the growth-rates equation (Table 8) are unbiased. On the other hand, the levels equation involves upward bias on the capital coefficient and downward bias on the labor coefficient.

Given the wide diversity of the estimates for θ , α , and ρ reported by the eight tables

in this section, it seems that the assumptions we have added to Romer's model do not substantially improve the ability of his model to rationalize high-frequency data. We therefore agree with Romer's (1987 p. 186) view that data from more countries and longer epochs should provide additional and perhaps better information on the model's parameters, and in particular, on θ . We look at cross-country data next.

III. Cross-Country Evidence on the Univariate Representation for y_t

Under certain assumptions, the Heston-Summers panel data on countries' GNP's will provide additional information on the parameters of the model. This is what we

examine next. We assume that all countries have the same production functions and tastes and that the only differences among them are their initial values for k_t , l_t , and z_t . In particular, z_t obeys the same process in all countries, although its realizations can vary. Because we shall be looking only at the y_t process,¹² and because l_t (in addition to k_t and z_t) will also be treated as unobservable, some further assumptions will now be added. First, we shall assume that $\lambda_1 = \lambda_2 = 0$ in equation (4), so that $\omega_t = \varepsilon_t$. This is done for analytical convenience, and it ought not to make much quantitative difference in this section, where we examine growth rates over a period of 25 years (and not at annual or quarterly growth rates, as was done in the previous section), so that the two-year moving average induced by the λ 's should not matter much, if at all. Second, we shall assume a particular stochastic process for the l_t sequence; in each country l_t is assumed to follow the stochastic process

$$l_t = m + rl_{t-1} + w_t \quad |r| \leq 1$$

where w_t is independently and identically distributed and independent of ε_t . We estimated this equation using U.S. annual data and OLS and obtained

$$l_t = -0.22 + 1.03l_{t-1} \quad R^2 = 0.98 \\ (0.18) \quad (0.02) \quad DW = 1.85.$$

Our maximum-likelihood results together with this suggest that, at least in the U.S., both ρ and r are quite close to unity. We shall then take the bold step of assuming that this is true in all the countries in the Heston-Summers sample.¹³

A. *Gibrat's Law in Growth of GNP*

Although, even under these additional assumptions, a study of the y_t process on its own will not identify θ , it will nevertheless rule out a great many possible values that the pair of crucial parameters (ρ, θ) can assume. One source of information about the behavior of y_t in 115 countries comes from the Heston-Summers sample (which is now updated to 1985). The regression below represents the relationship between the average 1960–1985 rate in GNP growth of a country on the one hand, and its 1960 GNP on the other.¹⁴ That is, the growth of countries is regressed on their initial size. The regression results reveal no significant relation between the two:

$$(8) \quad \Delta y_i = 0.047 - 0.0004 y_i \quad i = 1, \dots, 115 \\ (0.015) \quad (0.001) \\ \text{residual variance} = 0.0004$$

where y_i is the logarithm of 1960 GNP for country i and Δy_i is its growth per year over the 1960–1985 period (standard errors are in parentheses). Thus, the updated sample roughly confirms the nonsignificant relationship between growth and initial size that others have found,¹⁵ a (non-) relation that is in other contexts often referred to as "Gibrat's Law."

To find out what the seeming absence of a relation between size and growth means for our structural parameters, combine equations (2) and (5) to get

$$(9) \quad y_t = (\alpha + \theta)(\gamma + y_{t-1}) + \eta_t$$

¹²The Heston-Summers data set has information on population but not on the labor input. It also has no information on the capital input.

¹³Robert Barro's (1988) cross-country study of the univariate process for log(unemployment) (again, with annual data) revealed some significant cross-country differences in the degree of persistence in that variable. Nevertheless, at least in the postwar samples, the AR(1)-coefficient estimate typically does not differ significantly from unity. There are, however, good reasons to suspect the truth of our assumptions about l_t . First,

human capital should respond positively to ε_t , in much the same way as physical capital. This would tend to induce a positive correlation between l_t and ε_t . On the other hand, fertility responds negatively to income, and this would tend to induce a negative correlation between l_t and longer lags of ε_t .

¹⁴Kuwait was excluded from the regression, as it is an extreme outlier.

¹⁵This finding is for countries as a group, most of which are small and have little R&D investment. For industrialized countries, the result is somewhat different (see William Baumol and Edward Wolff, 1988; Bradford DeLong, 1988).

where $\eta_t \equiv (1 - \alpha)l_t + z_t$. Repeated substitution for lagged y 's leads to the following predicted relation between growth and initial size:

$$(10) \quad y_{t+T} - y_t = [(\alpha + \theta)^T - 1]y_t + \left(\sum_{j=0}^{T-1} (\alpha + \theta)^j \right) \times [(\alpha + \theta)\gamma + \eta_{t+T-j}].$$

The form of equations (9) and (10) depends, of course, on the savings rule in equation (5), and the theoretical justification that we provide for this savings rule rests on the assumption that capital depreciates fully each period. However, this section and the next both look at data at a frequency no greater than once every 25 years, and so this assumed depreciation rate may approximate reality quite well in this context.

Without further work, equation (10) cannot be used to interpret the regression results reported in equation (8), because y_t will be correlated with the disturbance in (10). One can see this by assuming that $r = \rho$, so that $\eta_t = (1 - \alpha)m + \mu + \rho\eta_{t-1} + \varepsilon_t + (1 - \alpha)w_t$, and by recursively substituting for lagged η 's in (7) to obtain

$$(11) \quad \eta_{t+T-j} = \rho^{T-j}\eta_t + (T-j)[\mu + (1 - \alpha)m] + \sum_{s=0}^{T-1-j} \rho^j v_{t+T-j-s}$$

where $v_t \equiv \varepsilon_t + (1 - \alpha)w_t$. As long as $\rho > 0$, innovations in η tend to persist, and η_t and y_t will be positively correlated for each country. Substituting from (11) into (10) then implies that the least-squares estimate of b in the regression $\Delta y_t = a + by_t$ is *identically*

$$(12) \quad \hat{b} = (\alpha + \theta)^T - 1 + \left\{ \left[\text{Cov}_i(\eta_{it}, y_{it}) / \text{Var}_i(y_{it}) \right] \times \sum_{j=0}^{T-1} (\alpha + \theta)^j \rho^{T-j} \right\}.$$

The subscript i on Cov_i and Var_i is there to emphasize that it is i that varies while t is held fixed at $t = 1960$.

To compute the expected value of \hat{b} , we invoke our assumption that the parameters of the y_t process are identical for all countries, in which case the empirical bivariate distribution of (y_{it}, η_{it}) over countries i at t approximates the stationary distribution of (y_t, η_t) for a given country when this distribution exists. When either $\rho \rightarrow 1$, or $(\alpha + \theta) \rightarrow 1$, this distribution blows up,¹⁶ but Appendix 1 shows that the ratio $\text{Cov}(y, \eta) / \text{Var}(y)$ still converges:

$$(13) \quad \lim_{r, \rho \rightarrow 1} [\text{Cov}(\eta_t, y_t) / \text{Var}(y_t)] = 1 - (\alpha + \theta).$$

Substituting from (13) into (12) and noting (once more from Appendix 1) that

$$\lim_{\rho \rightarrow 1} \sum_{j=0}^{T-1} (\alpha + \theta)^j \rho^{T-j} = [1 - (\alpha - \theta)^T] / [1 - (\alpha + \theta)]$$

yields

$$(14) \quad \lim_{\rho \rightarrow 1} E(\hat{b}) = (\alpha + \theta)^T - 1 + \{[1 - (\alpha + \theta)] \times [1 - (\alpha + \theta)^T] / [1 - (\alpha + \theta)]\} = 0.$$

Therefore, if ρ and r are roughly 1, Gibrat's Law will hold *regardless of the value of θ* . This means that the failure of GNP levels to converge does not identify θ .

¹⁶Because y_t acquires a permanent component if $\rho = 1$ or if $\alpha + \theta = 1$. Therefore, the findings of Charles Nelson and Charles Plosser (1982), John Campbell and Gregg Mankiw (1987), and John Cochrane (1988)—that one cannot reject the hypothesis that, in the univariate ARMA representation of GNP, innovations to GNP have a permanent component—do not, by themselves tell us whether $\alpha + \theta = 1$, or whether ρ or r is equal to unity.

As a caveat, we point out that our analysis treats countries as closed economies and looks for scale effects or spillover effects within but not across countries. Yet, geographical borders are in some respects an arbitrary division of geographical space and are therefore "noisy" measures of market areas within which, according to our analysis (and Romer's), these scale or spillover effects are assumed to be confined. Nevertheless, differences in culture and language and the presence of capital controls and other trade barriers do support the use of geographical borders to delineate the extent of the market.¹⁷

B. Growth in the Cross Section and in the Time Series

A second set of questions emerges from our assumption that the bivariate distribution of (y, η) among countries at a point in time is the same as the stationary distribution of (y, η) for a given country over time. The first point to note here is that the truth of this hypothesis is completely independent of the length of the epochs (T_{it}); instead, it has to do with how long the stochastic processes y_{it} have followed the law of motion (9) and with the speed of convergence to the stationary distribution implied by the parameters $\alpha + \theta$, ρ , and r .

The assumption that the cross-section distribution coincides with the stationary distribution can also be tested. Let g_{it} be

FIGURE 1. THE EMPIRICAL DISTRIBUTION OF COUNTRY-SPECIFIC VARIANCES OF GROWTH

the growth rate of GNP in country i between periods t and $t + 1$. If the hypothesis is true, the distribution of g_{it} ($t = 1960, \dots, 1984$) for each fixed i should be roughly the same as the distribution of g_{it} ($t = 1, \dots, 115$) for each fixed i .¹⁸ In particular, if σ_i^2 and σ_t^2 are the variances of the two respective distributions, we should have $\sigma_i^2 \approx \sigma_t^2$, at least for most i and most t . In fact, σ_i^2 and σ_t^2 both vary considerably as i and t vary, although *on average* they are roughly the same:

$$\left(\frac{1}{115} \right) \sum_{i=1}^{115} \sigma_i^2 = 0.0035$$

$$\left(\frac{1}{25} \right) \sum_{t=1960}^{1984} \sigma_t^2 = 0.0034.$$

The variability of σ_i^2 is documented in Table 9, and the variability of σ_t^2 is described in

¹⁷Of course, if significant cross-country spillovers in knowledge do exist, they surely run mainly from the rich nations toward the poor ones, and if so, they represent a force in support of convergence. In our model, the parameter μ presumably depends inversely on what is known domestically relative to what is known abroad. Two models of learning in situations where different agents know different things are presented in Jovanovic and Rafael Rob (1989) and Jovanovic and Glenn MacDonald (1988). In both of these theoretical models, those who are further behind learn more (through imitation) than those who are closer to the leaders, simply because they have more to learn. This argues for a higher μ for the poorer nations. However, such a perspective ignores the constraints on the capacity of people in a developing country to absorb and apply the technologies that the more advanced countries have already created and put in place (see Raymond Vernon [1989] for a viewpoint that emphasizes these constraints).

¹⁸Actually, this is true only if g_{it} and g_{jt} are independent random variables for $i \neq j$. In fact, Table 9 reveals significant time effects in the world's mean growth rates, especially after the first oil shock. This seems to imply a fair degree of contemporaneous covariation in countries' growth rates from 1974 on. If so, the variance of growth rates over countries at a given date should in fact be less than the variance of growth rates over time in a single country.

TABLE 9—MEAN AND VARIANCE OF THE
CROSS-COUNTRY DISTRIBUTION OF
YEAR-TO-YEAR GROWTH RATES IN GNP

Year	Mean	Variance (σ_t^2)
1961	0.0509	0.0034
1962	0.0528	0.0038
1963	0.0497	0.0023
1964	0.0527	0.0036
1965	0.0498	0.0032
1966	0.0487	0.0034
1967	0.0427	0.0023
1968	0.0536	0.0024
1969	0.0559	0.0030
1970	0.0543	0.0027
1971	0.0493	0.0027
1972	0.0511	0.0029
1973	0.0577	0.0036
1974	0.0429	0.0036
1975	0.0185	0.0059
1976	0.0526	0.0027
1977	0.0398	0.0028
1978	0.0453	0.0030
1979	0.0323	0.0052
1980	0.0327	0.0037
1981	0.0210	0.0061
1982	0.0023	0.0029
1983	0.0133	0.0033
1984	0.0362	0.0046
1985	0.0263	0.0020

Notes: Data are from the Heston-Summers sample, with Kuwait excluded. Growth rates are over the previous year.

the histogram in Figure 1 (in which Iraq, whose $\sigma_t^2 \times 1,000 = 30$, was omitted).¹⁹ A comparison of Table 9 and Figure 1 reveals that the variability of σ_t^2 is greater than that of σ_i^2 , which is what one would expect (if in truth they were equal) on sampling grounds since (a) σ_t^2 averages the variance of g_{it} over 115 countries, while σ_i^2 averages it over 25 years only, and (b) for fixed i , the observations g_{it} are autocorrelated.

C. Medium-Run Differences in Growth Among Countries

While the variability of growth rates among countries does not seem to differ from the variability of growth rates within

¹⁹It turns out that σ_t^2 is significantly negatively correlated with $y_{i,1960}$. That is, initially larger countries have less-variable growth rates. For instance, for the United States, $\sigma_t^2 = 0.0006$.

countries, one might still wonder whether differences in growth rates among countries are too *persistent* to be consistent with our model. The model asserts that, except for initial conditions, the η_t process is the same over countries. One way to pose the question about persistence is to ask about the cross-country variance of the mean growth rates over the 25-year periods. That is, does the model allow for a reasonable chance that some countries will grow much faster than others over a period as long as 25 years, or is this possibility a remote one?

The variance of growth within a country over time ultimately depends on the variance of the process $\eta_t = \varepsilon_t + (1 - \alpha)w_t$. The first step is to see what values of σ_ε^2 and σ_w^2 are compatible with the variance of 25-year annualized growth rates. In Appendix 1, we have calculated the variance of the steady-state distribution of Δy as a function of σ_w^2 and σ_ε^2 . Since $\Delta k_t = \Delta y_{t-1}$, the steady-state variance of Δy coincides with that of Δk , and this expression is provided in Table A1 (Appendix 2), where it is denoted by a_{kk} . If we hypothesize the truth of the Solow neo-classical model and insert $T = 25$, $\theta = 0$, and $\alpha = \frac{1}{3}$ in this expression, it reads $a_{kk} = 24\sigma_w^2 + (48.5)\sigma_\varepsilon^2$. This expression, when divided by 25^2 , should equal the *empirical* value of the cross-country variance of the 25-year averaged growth rates. This value turns out to be equal to slightly less than the variance of the residual in equation (8), namely 0.000355. Thus, setting $a_{kk}/25^2$ equal to this number yields a linear restriction on σ_w^2 and σ_ε^2 , namely

$$(24\sigma_w^2 + 48.5\sigma_\varepsilon^2)/25^2 = 0.000355.$$

This is the restriction on σ_w^2 and σ_ε^2 that will generate the medium-run growth differentials across countries that we observe.

If one were to substitute the U.S. values for σ_w^2 and σ_ε^2 into the above expression, one would obtain an expression for its left-hand side, that is much smaller than the right-hand side. If ρ and r are both unity, one can estimate σ_w^2 and σ_ε^2 by the variance of Δl and Δz , respectively. Doing this for the postwar annual U.S. data yields $\sigma_w^2 =$

0.00044 and $\sigma_e^2 = 0.00037$.²⁰ Substituting these values into the above expression yields just 0.000046, which is too small by a factor of 7.7.

This is not the end of it, however, because of the heteroskedasticity of growth rates over countries. The variance of the U.S. growth rate is 0.0006, whereas the growth-rate variance for the median country is about 0.003, and its mean is 0.0035. Therefore, the variability of growth in the "average" country exceeds that of the United States by a factor of about 5 or 6. Since the U.S. variability underestimates the right-hand side of the above equation by a factor of 7.7, it is likely that, if we had estimates of σ_w^2 and σ_e^2 from the *average* country, we would have explained roughly 65–78 percent of the cross-country variability in growth rates. The discrepancy is therefore far smaller than one would have thought; to account for it, one or more of the parameters that we have assumed to be the same for all countries might have to be made country-specific.²¹

The above arguments suggest that the augmented Solow model with $\theta = 0$ is consistent with the bulk of cross-country growth differentials in the medium run. However, it is clearly not consistent with the tremendous heteroskedasticity in yearly growth rates that Figure 1 highlights, although such

heteroskedasticity could also have been produced by measurement errors with country-specific variances.

While the above discussion leaves some unanswered questions about our model's ability to explain (a) the lack of convergence of GNP *levels* and (b) the existence of persisting differentials in growth *rates*, we should in all fairness point out that an alternative explanation for (a) and (b) simultaneously, is as yet unavailable. For instance, in Romer's (1987) model, with a constant savings propensity tacked on, $\alpha + \theta > 1$ ($\alpha + \theta < 1$) implies that the growth rate will be positively (negatively) correlated with the size of the capital stock, while $\alpha + \theta \approx 1$ implies independence. Under independence, which seems supported by data, differences in growth rates among countries must be due either to differences in technology and savings rates or to shocks. The mere presence of externalities ($\theta > 0$) does not by itself account for differences in growth rates.

IV. The Relation Between Inputs and Output Over Longer Epochs

Consider a regression such as the one that Romer (1987) reports in his equation 18. In country i , over a period length T_{it} , differences in the growth of inputs and outputs are calculated, so that, for instance, $\Delta y_{it} \equiv y_{i,t+T_{it}} - y_{it}$. That is, the regression is

$$(15) \quad T_{it}^{-1} \Delta y_{it} = b + b_k T_{it}^{-1} \Delta k_{it} + b_l T_{it}^{-1} \Delta l_{it} + u_{it}.$$

Romer uses 18 observations that span seven countries (subscript i), and four epochs (subscript t) of at least 30 years in length; the measure of the labor input is hours worked. The least-squares regression results that he reports in his equation 18 are: $\hat{b}_k = 0.87$ with a standard error of 0.08, and $\hat{b}_l = 0.04$ with a standard error of 0.18. Our aim here is to calculate the expectations of \hat{b}_k and \hat{b}_l in light of the added assumptions that we have imposed on the evolution of k , l , and z . The least-squares estimates of the coefficients, denoted by carets, are identi-

²⁰The covariance between Δl and Δz is 0.00012. Ignoring it, as we do here, hurts rather than helps our case. Note also that the estimate of σ_e^2 that we have calculated here is actually consistent with its estimates for the annual data in Tables 1 and 2, because, since we are assuming no moving-average terms in this section, the relevant comparison is with $(1 + \lambda_1^2 + \lambda_2^2)\sigma_e^2$ in those tables.

²¹For instance, the parameter μ might have to be made country-specific. Country-specific fixed effects are, in this context at least, simply a label for one's ignorance, and the calculations about variances reported in the above paragraph are too rough and tentative to convince us that the country-specific fixed effect is needed here. Our z_{it} 's are, we submit, less objectionable, because they at least are stochastically equal among countries, although their particular realizations can vary. Moreover, even if ρ and r are unity, the long-run growth rate of z is just μ for each country, and there can be no long-run differences in growth. We discuss this in greater detail in the next section.

cally equal to²²

$$\begin{bmatrix} \hat{b} \\ \hat{b}_k \\ \hat{b}_l \end{bmatrix} = \begin{bmatrix} 0 \\ \alpha + \theta \\ 1 - \alpha \end{bmatrix} + \begin{bmatrix} n & \bar{k} & \bar{l} \\ \bar{k} & a_{kk} & a_{kl} \\ \bar{l} & a_{kl} & a_{ll} \end{bmatrix}^{-1} \begin{bmatrix} \bar{a} \\ a_{ku} \\ a_{lu} \end{bmatrix}$$

from which one can show that, since $Ea_{lu} = 0$ by equation (6),

$$\begin{aligned} (16) \quad E \begin{bmatrix} \hat{b}_k \\ \hat{b}_l \end{bmatrix} &= \begin{bmatrix} \alpha + \theta \\ 1 - \alpha \end{bmatrix} + \left(E \frac{1}{a_{kk}a_{ll} - a_{kl}^2} \right. \\ &\quad \times \begin{bmatrix} a_{ll} & -a_{kl} \\ -a_{kl} & a_{kk} \end{bmatrix} \begin{bmatrix} a_{ku} \\ 0 \end{bmatrix} \Bigg) \\ &= \begin{bmatrix} \alpha + \theta \\ 1 - \alpha \end{bmatrix} + \left(E \frac{1}{a_{kk}a_{ll} - a_{kl}^2} \right. \\ &\quad \times \begin{bmatrix} a_{ll}a_{ku} \\ -a_{kl}a_{ku} \end{bmatrix} \Bigg). \end{aligned}$$

Since the a_{ij} are all positive, \hat{b}_k will be biased upward while \hat{b}_l will be biased downward, with the bias on \hat{b}_k equalling $-a_{ll}/a_{kl}$ times the bias on \hat{b}_l . Appendix 2 calculates the a_{ij} on the assumption that all countries are subject to the same stochastic process but face different realizations of the ε 's and w 's, as well as different initial condi-

tions. The resulting expressions for the a_{ij} 's are quite messy, but the following limiting results are worth noting.²³

$$(17) \quad \lim_{r, \rho \rightarrow 1} \left\{ \lim_{T \rightarrow \infty} [E(\hat{b}_k)] \right\} = 1$$

$$(18) \quad \lim_{r, \rho \rightarrow 1} \left\{ \lim_{T \rightarrow \infty} [E(\hat{b}_l)] \right\} = 0.$$

These results are of relevance if the epochs (which are of length T) are long and if z and l are roughly random walks, as appears to be the case empirically. Therefore, $E(b_l)$ is zero, regardless of the relative values of σ_ε^2 and σ_w^2 , while $E(\hat{b}_k) = 1$ if $\sigma_w^2 = 0$. These expected values are of course not far from Romer's actual estimates, $\hat{b}_k = 0.87$ and $\hat{b}_l = 0.04$.

Table A1 of Appendix 2 reports the expressions for the a_{ij} that one can use to calculate the bias in the least-squares estimates \hat{b}_k and \hat{b}_l for the cases in which (a) T remains finite but ρ and r tend to unity and (b) ρ and r are less than unity but T goes to infinity. In both cases, the bias remains positive but is difficult to represent analytically in a compact way. The main point is that the limiting values expressed in equations (17) and (18) are good approximations for the values that \hat{b}_k and \hat{b}_l would be expected to take for large T and for r and ρ reasonably close to 1.

Equations (17) and (18) are the same as what Christiano (1987) obtains under a different but related set of assumptions. He allows for country-specific fixed effects μ_i in (3) and m_i in the equation governing the evolution of l , while assuming $\rho = r = 1$ and $\sigma_w^2 = 0$. His theoretical results also assume $\sigma_w^2 = 0$, while his simulations allow for $\sigma_w^2 > 0$; both yield the analogues of (17) and (18), and he argues, as we do, that the results

²²This equation follows directly from the application of the least-squares formula. The number of observations (i.e., the number of country-epoch pairs) is n . The a_{ij} are the raw moments. For instance, $a_{kl} = \sum_{i,t} T_{it}^{-2} \Delta k_{it} \Delta l_{it}$, and so on. The variables with overbars are the mean growth rates over the sample. For instance, $\bar{k} = \sum_{i,t} T_{it}^{-1} \Delta k_{it}$, and so on.

²³We present the results only for this particular limiting case because the general expressions would be very lengthy. Table A1 in Appendix 2 presents results that make it possible to compute $E(\hat{b}_k)$ and $E(\hat{b}_l)$ for finite T or for ρ and r less than unity.

that Romer reports in his equation (18) are consistent with θ being 0.

Several additional insights follow from our analysis, however. In explaining these, it is worthwhile to elaborate on the differences between our model and Christiano's (1987) fixed-effects model. These differences are best explained under the assumption that $\sigma_w^2 = 0$ (i.e., that labor supply is nonrandom). In the fixed-effects model, a country's long-run growth rate is $\mu_i/(1-\alpha)$. In our model, the long-run growth rate for z is

$$\lim_{T \rightarrow \infty} T^{-1} \sum_{t=1}^T (z_{t+1} - z_t) = \begin{cases} \mu & \text{if } \rho = 1 \\ 0 & \text{if } \rho < 1. \end{cases}$$

Since μ is the same over countries, countries must, in the long run, all grow at the same rate regardless of the value of ρ . Thus, a fixed-effects model delivers a positive variance of long-run growth rates among countries, while ours does not.²⁴ Our view gets further support from recent empirical work by Danny Quah (1990), who argues that, in the Heston-Summers data, income growth rates show convergence to a common value.

In our model, the upward bias on the capital coefficient is positively related to ρ . Continuing with the case in which labor input is nonrandom ($\sigma_w^2 = 0$), we find from the second column of Table A1 that, as T approaches ∞ , the bias on the capital coefficient approaches

$$\frac{\rho[1 - (\alpha + \theta)^2]}{1 + \rho(\alpha + \theta)}.$$

As ρ goes to unity, so that (18) obtains, the bias becomes $1 - (\alpha + \theta)$, while as ρ goes to zero, the bias becomes zero.

The conclusion we draw from this exercise is the same as the one Christiano draws: the regression results that use data on long-run movements of output and both inputs

also provide no support for the hypothesis that θ is significantly positive.

Aside from the hypotheses that Romer, Christiano, and we have advanced, yet another argument can be advanced to rationalize the high estimated coefficient of Δk and the low estimated coefficient of Δl : the growth of the physical capital stock may be strongly positively correlated with growth of labor quality, while growth in hours worked may be negatively related to the growth of labor quality. The latter association is well documented at high frequencies in the micro data, and Romer's (1987) figure 1 provides some indirect evidence for it at lower frequencies for the United States. Since the empirical estimates of equation (15) use hours worked unadjusted for quality, this would tend to cause an upward bias on capital's coefficient and a downward bias on labor's coefficient. This hypothesis, which does not revolve around either external effects or increasing returns, still awaits a careful theoretical treatment, but whatever its eventual fate, it is important to bear in mind that it is independent of the other hypotheses discussed here. Of course, if one were to insist that increases in the capital stock *cause* measured equiproportionate improvements in unmeasured labor quality, then one is back in a framework captured by equation (1), with, say \bar{K}^θ denoting unmeasured labor quality, and this is a framework that the data do not seem to support.

V. Microfoundations of the Model

Our remaining task is to provide a firmer analytic foundation for the equations used in our estimation process. The key element driving the results that stem from the structural equations (2)–(5) and assumption (6) is the dependence of the capital stock, through savings behavior, on the stochastic shock to production in the previous period. If this shock is serially correlated, current output will also depend on the shock in the previous period. Therefore, the correlation of contemporaneous output and capital not only reflects the internal and external impact of contemporaneous capital on output but contains an additional component

²⁴Table A1 contains information about the speed of convergence to zero of variables such as a_{kk} , the variance of the long-run growth rate of capital stock. The table shows that this and other variances and covariances go to zero at the rate T^{-1} when $\rho = 1$, while they go to zero at the rate T^{-2} when $\rho < 1$.

through the joint dependence of output and capital on the previous productivity shock. Ignoring this element results in exaggeration of the importance of capital in production. In this section, we spell out a stochastic overlapping-generations (OLG) model as well as a stochastic Brock-Mirman type of growth model to justify the equations of the previous section, especially equation (5) and assumption (6).

We start with a special OLG model in which the representative agent in generation t faces a wage w_t and a stochastic rate of return on his savings, r_{t+1} . Therefore, his consumption in the second period of his life is $c_{t+1} = (w_t - c_t)r_{t+1}$. We assume that the agent has a logarithmic utility function

$$\beta \ln c_t + (1 - \beta) E \ln (w_t - c_t) r_{t+1}$$

which he maximizes by choosing c_t . The production function is assumed to be of Cobb-Douglas form with a multiplicative productivity shock and is given by (1).

Population growth is stochastic, so that $L_t = L_{t-1}(1 + N_t)$, where N_t is independently and identically distributed with mean zero. The wage rate and the interest rate are equal to the marginal products of labor and capital, respectively. Since the agent bases his saving decision on the marginal product of capital in the next period, he faces a stochastic interest rate (on account both of the stochastic productivity shock and the stochastic growth of labor).

The agent's optimal savings do not depend on the interest rate, so that $s_t = (w_t - c_t) = (1 - \beta)w_t$. Thus, the total savings, which determine next period's capital stock, are

$$\begin{aligned} s_t L_t &= K_{t+1} = (1 - \beta)(1 - \alpha) Z_0 K_t^{\alpha + \theta} L_t^{1 - \alpha} \\ &= (1 - \beta)(1 - \alpha) Y_t \end{aligned}$$

since the share of labor is the fraction $1 - \alpha$ of output. Taking logarithms immediately yields equation (5) and assumption (6) of the previous section.

Before moving on to the infinite-horizon model, we should discuss the role of specific functional forms and assumptions. The log-

arithmic utility function simplifies matters considerably by eliminating the dependence of savings on the next-period rate of return; but its use in this context goes beyond algebraic convenience. Slightly altering the utility function, say to one with a constant relative risk aversion, may yield a savings function that either increases or decreases with the rate of interest, depending on whether the risk-aversion coefficient is less than or greater than unity in absolute value. Since an increase in the productivity shock leads to an expected increase in the shock next period and raises the expected interest rate, productivity shocks may in fact decrease savings and next period's capital stock if the direct wealth effect through wages is dominated, resulting in a *negative* correlation between K_{t+1} and Z_{t+1} and contradicting equation (5) in the previous section. (This issue will also arise in the infinite-horizon model considered below.) In drawing generalizations from the example, therefore, we should keep in mind that we may need a preference specification for which savings are a nondecreasing function of the interest rate.²⁵

We now turn to the specification with an infinitely lived representative agent. Before exploiting specific functional forms, we present a general version to pinpoint again the role of the assumptions embodied in our specific functional forms.

The representative agent has an instantaneous, twice-differentiable utility function $U(c_t, a_t - L_t)$, defined on feasible consumption and leisure sets, where a_t is a stochastic labor endowment and L_t is the labor supply. We may specify a_t as a multiplicative Markov process to reflect population growth, since the actual supply of labor will be endogenously chosen. The twice-differentiable production function is given by

²⁵Another set of problems that plague the OLG model relates to the continuum of equilibria. While our special specification avoids these problems, multiplicities will arise either if outside money is introduced as an additional asset or if the labor-supply decision is endogenized and the logarithmic specification of utility is dropped (for a detailed analysis see Benhabib and Guy Laroque [1988]).

$Y_t = Z_t f(K_t, \bar{K}_t, L_t)$, where Z_t is the stochastic shock to the production function and \bar{K}_t ($\equiv K_t$) enters the production function to reflect an externality. Let δ be the depreciation rate of capital. The agent, facing constraints $K_{t+1} = Z_t f(K_t, \bar{K}_t, L_t) + (1 - \delta)K_t - c_t$ and a given K_0 , maximizes $E \sum_0^\infty \beta^t U(c_t, a_t - L_t)$ by choosing each c_t and L_t after observing Z_t and a_t at every t . In dynamic programming form, the problem can be expressed as

$$V(K_0, Z_0, a_0) = \max_{K_1, L_0} U(Z_0 f(K_0, \bar{K}_0, L_0) + (1 - \delta)K_0 - K_1, a_0 - L_0) + \beta EV(K_1, Z_1, a_1).$$

To simplify matters, we assume that the value function V is twice-differentiable in (K, Z) . (The twice-differentiability of V in certain stochastic cases can be established by the methods of Lawrence Blume and David Easley [1982]). Let the derivatives of $V(K, Z, a)$ with respect to K and Z be denoted by V_K and V_Z and let the second-order derivatives be denoted by V_{KK} , V_{KZ} , and V_{ZZ} . Similarly, let U_c and U_L be the derivatives of the utility function with respect to consumption and leisure, with second derivatives U_{cc} , U_{cL} , and U_{LL} . Again, for simplicity, we will assume that $U_{cL} = 0$. Finally, let the derivatives of the production function be denoted by f_K , $f_{\bar{K}}$, and f_L . Standard methodology establishes the first-order conditions for the representative agent's problem with the usual interpretation:

$$(19) \quad U_c(Z_0 f(K_0, \bar{K}_0, L_0) + (1 - \delta)K_0 - K_1, a_0 - L_0) = \beta V_K(K_1, Z_1, a_1).$$

$$(20) \quad U_c(Z_0 f(K_0, \bar{K}_0, L_0) + (1 - \delta)K_0 - K_1, a_0 - L_0) \times Z_0 f_L(K_0, \bar{K}_0, L_0) = U_L(Z_0 f(K_0, \bar{K}_0, L_0) + (1 - \delta)K_0 - K_1, a_0 - L_0).$$

From equation (20), we can obtain the optimal-labor-supply function as $L_0 = L(K_1, K_0, \bar{K}_0, a_0, Z_0)$. Let L_0^Z and L_0^K indicate the derivatives of L_0 with respect to Z_0 and K_0 .

As discussed earlier, we want to investigate the effect of Z_t on K_{t+1} to establish the nature of the covariance between K_{t+1} and Z_{t+1} . Using (19) and (20),

$$dK_1/dK_0 = [(U_{LL} + U_c Z_0 f_{LL})(U_{cc} Z_0 F_K - U_{cc} Z_0 f_L U_c Z_0 f_{KL})]/D > 0$$

and

$$dK_1/dZ_0 = [(U_{LL} + U_c Z_0 f_{LL}) \times (U_{cc} f - \beta EV_{KZ} dZ_1/dZ_0) - U_{cc} Z_0^2 f_L^2 \beta EV_{KZ} dZ_1/dZ_0]/D$$

where

$$D \equiv (U_{LL} + U_c Z_0 f_{LL})(U_{cc} + \beta EV_{KK}) + \beta EU_{cc} V_{KK} Z_0^2 f_L^2 > 0$$

$$F_K \equiv f_K(K_0, \bar{K}_0, L_0) + f_{\bar{K}}(K_0, \bar{K}_0, L_0) + (1 - \delta)$$

and where V_{KK} and V_{KZ} are evaluated at (K_1, Z_1, a_1) . The policy function $K_1 = h(K_0, Z_0)$ is therefore increasing in K_0 .²⁶ Also, $dK_1/dZ_0 > 0$ if $V_{KZ} > 0$. To evaluate V_{KZ} we first compute

$$V_K(K_0, Z_0, a_0) = U_c Z_0 [f_K + f_{\bar{K}} + (1 - \delta)]$$

²⁶This monotonicity property can be established rigorously without assuming the differentiability of the value function. A proof is in Benhabib and Kazuo Nishimura (1989), in lemma 1 of that of paper's appendix. Although the model there is slightly different, with very minor modifications the proof applies to the present case.

to obtain

$$\begin{aligned} V_{kz}(K_0, Z_0, a_0) \\ = U_c((U_{cc}/U_c)(\partial c_0/\partial Z_0)Z_0 + 1) \\ \times (f_k + f_{\bar{k}} + (1 - \delta)) \\ + U_c Z_0 f_{kL}(dL(K_0, \bar{K}_0, Z_0, a_0)/dZ_0). \end{aligned}$$

The sign of V_{kz} and therefore of dK_1/dZ_0 is ambiguous for the same reasons as in the OLG case. First it depends on the degree of relative risk aversion in the term $(U''/U')(\partial c/\partial Z_0)Z_0 + 1$: if this term is sufficiently negative, $\partial K_1/\partial Z_0$ may become negative. Furthermore, unlike our specification in the OLG model, the labor supply is endogenous. An increase in Z_0 , through its effect on Z_1 , leads to an increase in the expected interest rate and may produce not only lower savings but also a lower labor supply; that is, we may have $dL/dZ < 0$. This also tends to make V_{kz} negative, and if sufficiently strong, may result in $dK_1/dZ_0 < 0$. In the special case of a logarithmic utility function coupled with a Cobb-Douglas production function and full depreciation ($\delta = 1$), V_{kz} is identically zero, as can be easily computed using the solution of this special case, reported below. Therefore, for our purposes, it seems that the main restrictions imposed by a model with logarithmic utility and Cobb-Douglas production with full depreciation are to eliminate the possibility of a saving policy and a labor supply which both decrease in response to increases in the rate of return. To see this, consider the policy function for the general case given by $K_1 = h(K_0, Z_0)$ and assume that $\partial h/\partial Z_0 > 0$. We then have the following lemma.

LEMMA 1: *Let $K_{t+1} = h(K_t, Z_t)$, where h is strictly increasing. If Z_t follows the process described by equations (3) and (4) with $\lambda_i \geq 0$ ($i = 1, 2$), then k_t is stochastically strictly increasing in z_t .*

PROOF:

Recursive substitution for lagged capital shocks in h yields $k_t = \phi(z^t)$, where $z^t \equiv$

$(z_{t-1}, z_{t-2}, \dots)$ and where ϕ is strictly increasing. Applying Bayes' rule along with equation (2) yields that for any vector $\bar{z} \in \mathbb{R}$, $\Pr\{z^t \leq \bar{z} | z_t\}$ is stochastically strictly increasing in z_t , and the claim follows.

A corollary of the lemma is that the steady-state covariance between k_t and z_t is strictly positive, and this is all that is required for an upward bias on the capital coefficient in an ordinary-least-squares context.

The advantage of specifying log utility and Cobb-Douglas production with full depreciation is that we can solve explicitly for the optimal consumption, savings, and labor-supply policies. Using (19) and (20) and adopting the logarithmic instantaneous utility function

$$\lambda \ln c + (1 - \lambda) \ln(a - L)$$

together with the Cobb-Douglas production function $Z_0 K^\alpha \bar{K}^\theta L^{1-\alpha}$, it can easily be verified that savings, or next period's capital stock, will be

$$(21) \quad K_1 = \alpha \beta Z_0 K_0^{\alpha+\theta} L_0^{1-\alpha}$$

and that labor supply is given by

$$(22) \quad L_1 = \frac{\lambda(1-\alpha)a_t}{(1-\lambda)(1-\alpha\beta) + \lambda(1-\alpha)}.$$

If the random endowment follows a multiplicative first-order Markov process, then after taking logarithms, (21) and (22) correspond exactly to equation (5) and assumption (6). Note that, to make labor supply stochastic, we could have made the taste parameter stochastic rather than assume a stochastic endowment. Alternatively, if a , λ , and other relevant parameters in (22) were constant, labor supply would be as well, and we would run into identification problems in the previous section. (Note that, in the general specification of the model, labor would be stochastic even if a and λ were fixed.)

We conclude, therefore, that the specifications represented by equation (5) and assumption (6), which drive our results in the

previous section and which underlie our empirical conclusions, can be obtained under reasonable assumptions in either the OLG or the infinitely-lived-agent models of stochastic growth.

VI. Conclusions

Given our assumption that knowledge causes capital but not the other way around, our failure to find a positive θ implies nothing whatsoever about externalities in the generation of knowledge. The Solow model with no externalities to either labor or capital but with stochastic shocks to knowledge does not appear to be contradicted by long-run data on output and the two inputs; furthermore, it is also consistent with micro evidence on knowledge spillovers. The apparent validity of Gibrat's law in countries' GNP series does not contradict it, nor do the seemingly sizable medium-run differentials in growth rates over countries. Moreover, the model fits in with the recent business-cycle literature that explains properties of cycles with productivity shocks.

The realizations of our technology shocks, the z 's, are allowed to differ over countries, but the stochastic process forming them is assumed to be the same, as indeed are all the parameters of our model. That technology shocks can assume different values over countries seems reasonable if one interprets these shocks broadly to include shifts in institutional and organizational structures, such as shifts in the corporate, legal, or bureaucratic structures, or even in attitudes toward work. These elements can greatly enhance or retard the effective use and operation of factors of production. While such changes in institutional or organizational structures may not be permanent, they tend to be quite persistent, so that productivity in different economies can diverge for extended periods of time.

No doubt, a quantum leap in our understanding of growth will occur only when the engine of growth, namely the z_t process, is successfully endogenized. What we think we have shown here, however, is that this engine is fueled primarily by something other than physical capital.

APPENDIX

Appendix 1: The Derivation of Equation (13)

Note first that

$$\sum_{j=0}^{T-1} (\alpha + \theta)^j \rho^{T-j} = \rho^T \frac{1 - [\alpha + \theta/\rho]^T}{1 - (\alpha + \theta)/\rho}.$$

If $(\alpha + \theta) = \rho$, this expression is equal to $T\rho^T$. Next, note from equations (2) and (5) that $k_{t+1} = \gamma + (\alpha + \theta)k_t + \eta_t$, where $\eta_t = (1 - \alpha)l_t + z_t$. Then,

$$\begin{aligned} \text{Cov}(\eta_t, k_t) &= \text{Cov}(\eta_t, (\alpha + \theta)k_{t-1} + \eta_{t-1}) \\ &= (\alpha + \theta)\text{Cov}(\eta_t, k_{t-1}) \\ &\quad + \text{Cov}(\eta_t, \eta_{t-1}). \end{aligned}$$

Expanding further, we obtain

$$\begin{aligned} \text{(A1)} \quad \text{Cov}(\eta_t, k_t) &= \sum_{j=1}^{\infty} (\alpha + \theta)^{j-1} \text{Cov}(\eta_t, \eta_{t-j}). \end{aligned}$$

Since $(1 - \alpha)l_t = (1 - \alpha)m + (1 - \alpha)l_{t-1} + (1 - \alpha)w_t$, then if $\rho = r$,

$$\begin{aligned} \eta_t &= (1 - \alpha)m + \mu + \rho\eta_{t-1} \\ &\quad + (\varepsilon_t + (1 - \alpha)w_t) \end{aligned}$$

so that $\text{Cov}(\eta_t, \eta_{t-j}) = \rho^j \sigma_{\eta}^2$, where $\sigma_{\eta}^2 = [\sigma_{\varepsilon}^2 + (1 - \alpha)^2 \sigma_w^2] / (1 - \rho^2)$. Then, using (A1),

$$\begin{aligned} \text{(A2)} \quad \text{Cov}(\eta_t, k_t) &= \sigma_{\eta}^2 \sum_{j=1}^{\infty} \rho^j (\alpha + \theta)^{j-1} \\ &= \rho \sigma_{\eta}^2 / [1 - \rho(\alpha + \theta)]. \end{aligned}$$

From equation (2),

$$\text{Cov}(\eta_t, y_t) = (\alpha + \theta)\text{Cov}(\eta_t, k_t) + \sigma_{\eta}^2.$$

Substituting into this expression from (A2) or yields

$$\begin{aligned} (A3) \quad \text{Cov}(\eta_t, y_t) &= \sigma_\eta^2 \{1 + \rho(\alpha + \theta) / [1 - \rho(\alpha + \theta)]\} \\ &= \sigma_\eta^2 / [1 - \rho(\alpha + \theta)]. \end{aligned}$$

Next, we need to compute $\text{Var}(y_t)$. Since $y_t = (\alpha + \theta)k_t + \eta_t$,

$$\begin{aligned} (A4) \quad \text{Var}(y_t) &= (\alpha + \theta)^2 \text{Var}(k_t) + \sigma_\eta^2 \\ &\quad + 2(\alpha + \theta) \text{Cov}(\eta_t, k_t). \end{aligned}$$

Now, since $k_{t+1} = \gamma + y_t$, $\text{Var}(y_t) = \text{Var}(k_t)$. Using this in (A4) and substituting from (A3) into (A4) for $\text{Cov}(\eta_t, k_t)$ yields

$$\begin{aligned} (A5) \quad \text{Var}(y_t) &= \left(\frac{\sigma_\eta^2}{1 - (\alpha + \theta)^2} \right) \left(1 + \frac{2(\alpha + \theta)\rho}{1 - \rho(\alpha + \theta)} \right). \end{aligned}$$

The expressions in (A4) and (A5) both explode when ρ approaches 1, because σ_η^2 goes to infinity, but their ratio does not:

$$\lim_{\rho \rightarrow 1} [\text{Cov}(\eta, y) / \text{Var}(y)] = 1 - \alpha - \theta.$$

This is equation (13) of the text, since, by assumption, $\rho = r$.

Appendix 2

Here, we derive expressions for the a_{ij} in equation (16) under various assumptions. Deterministic components of z and l are ignored. We assume in equation (4) that $\lambda_1 = \lambda_2 = 0$, so that $\varepsilon_t = w_t$ and so that the w_t are also independently and identically distributed. Repeated substitution in (3) leads to

$$\begin{aligned} z_{t+T} &= \rho^T z_t + \rho^{T-1} \varepsilon_t \\ &\quad + \rho^{T-2} \varepsilon_{t+1} + \dots + \varepsilon_{t+T-1} \end{aligned}$$

$$\begin{aligned} \Delta^T z_t &\equiv z_{t+T} - z_t \\ &= (\rho^T - 1) z_t + \rho^{T-1} \varepsilon_t \\ &\quad + \rho^{T-2} \varepsilon_{t+1} + \dots + \varepsilon_{t+T-1}. \end{aligned}$$

However,

$$\begin{aligned} z_t &= \rho^{j+1} z_{t-j-1} + \rho^j \varepsilon_{t-j-1} + \rho^{j-1} \varepsilon_{t-j} \\ &\quad + \rho^{j-2} \varepsilon_{t-j+1} + \dots + \varepsilon_{t-1} \end{aligned}$$

so that

$$\begin{aligned} \Delta^T z_t &= (\rho^T - 1) \\ &\quad \times (\rho^{j+1} z_{t-j-1} + \rho^j \varepsilon_{t-j-1} + \dots + \varepsilon_{t-1}) \\ &\quad + \rho^{T-1} \varepsilon_t + \rho^{T-2} \varepsilon_{t+1} + \dots + \varepsilon_{t+T-1} \end{aligned}$$

and also

$$\begin{aligned} \Delta^T z_{t-j-1} &= (\rho^T - 1) z_{t-j-1} \\ &\quad + \rho^{T-1} \varepsilon_{t-j-1} + \rho^{T-2} \varepsilon_{t-j} \\ &\quad + \rho^{T-3} \varepsilon_{t-j+1} + \dots + \varepsilon_{t-j+T-2}. \end{aligned}$$

Note that subscripts on $\Delta^T z_t$ for the ε 's run from $t-j-1$ to $t-1+T$ and that subscripts on $\Delta^T z_{t-j-1}$ for the ε 's run from $t-j-1$ to $t-1+T-j-1$. We shall consider two separate cases: (i) $T-j-1 > 0$ and (ii) $T-j-1 \leq 0$, both for $j \geq 0$.

Case (i). For this case,

$$\begin{aligned} \text{Cov}(\Delta^T z_t, \Delta^T z_{t-j-1}) &= [\sigma_\varepsilon^2 / (1 - \rho^2)] [(\rho^T - 1)^2 \rho^{j+1}] \\ &\quad + \sigma_\varepsilon^2 (\rho^T - 1) \sum_{i=1}^{j+1} \rho^{j+1-i} \rho^{T-i} \\ &\quad + \sigma_\varepsilon^2 \sum_{i=1}^{T-j-1} \rho^{T-i} \rho^{t-j-1-i} \end{aligned}$$

$$\begin{aligned}
&= [\sigma_\varepsilon^2 / (1 - \rho^2)] (\rho^T - 1)^2 \rho^{j+1} \\
&\quad + \sigma_\varepsilon^2 (\rho^T - 1) \rho^{T+j-1} \\
&\quad \times [(1 - \rho^{-2(j+1)}) / (1 - \rho^{-2})] \\
&\quad + \sigma_\varepsilon^2 \rho^{2T-j-3} \\
&\quad \times [(1 - \rho^{-2(T-j-1)}) / (1 - \rho^{-2})].
\end{aligned}$$

As a check on the algebra, note that $\lim_{\rho \rightarrow 1} [\text{Cov}(\Delta^T z_t, \Delta^T z_{t-j-1})] = \sigma_\varepsilon^2 (T - j - 1)$, because the first term goes to zero by L'Hôpital's rule and the second term is zero. This result is exactly as expected.

Case (ii). For $(T - j - 1) \leq 0$,

$$\begin{aligned}
&\text{Cov}(\Delta^T z_t, \Delta^T z_{t-j-1}) \\
&= [\sigma_\varepsilon^2 / (1 - \rho^2)] (\rho^T - 1)^2 \rho^{j+1} \\
&\quad + (\rho^T - 1) \left(\sum_{i=1}^T \rho^{j+1-i} \rho^{T-i} \right) \sigma_\varepsilon^2.
\end{aligned}$$

Again, as a check on the algebra, note that $\lim_{\rho \rightarrow 1} [\text{Cov}(\Delta^T z_t, \Delta^T z_{t-j-1})] = 0$, as it should. As a further check, note that when $j = 0$, we have

$$\begin{aligned}
\text{Var}(\Delta^T z_t) &= [\sigma_\varepsilon^2 / (1 - \rho^2)] (\rho^T - 1)^2 \\
&\quad + [(\rho^{T-2} - \rho^{-2}) / (1 - \rho^{-2})] \sigma_\varepsilon^2
\end{aligned}$$

so that $\lim_{\rho \rightarrow 1} [\text{Var}(\Delta^T z_t)] = \sigma_\varepsilon^2 T$, as it should. Moreover, for $\rho < 1$,

$$\begin{aligned}
&\lim_{T \rightarrow \infty} [\text{Var}(\Delta^T z_t)] \\
&= \sigma_\varepsilon^2 / (1 - \rho^2) \\
&\quad + [-\rho^{-2} / (1 - \rho^{-2})] \sigma_\varepsilon^2 \\
&= 2\sigma_\varepsilon^2 / (1 - \rho^2).
\end{aligned}$$

Now we shall compute $\text{Cov}(\Delta^T k_t, \Delta^T z_t)$, first for arbitrary ρ and T , and then we shall

take limits. Combining cases (i) and (ii),

$$\begin{aligned}
&\text{Cov}(\Delta^T z_t, \Delta^T k_t) \\
&= \sum_{j=0}^{\infty} (\alpha + \theta)^j \text{Cov}(\Delta^T z_t, \Delta^T z_{t-j-1}) \\
&= \sum_{j=0}^{T-2} (\alpha + \theta)^j \text{Cov}(\Delta^T z_t, \Delta^T z_{t-j-1}) \\
&\quad + \sum_{j=T-1}^{\infty} (\alpha + \theta)^j \\
&\quad \times \text{Cov}(\Delta^T z_t, \Delta^T z_{t-j-1}) \\
&= \sum_{j=0}^{T-2} (\alpha + \theta)^j \\
&\quad \times \left\{ [\sigma_\varepsilon^2 / (1 - \rho^2)] (\rho^T - 1)^2 \rho^{j+1} \right. \\
&\quad \quad + \sigma_\varepsilon^2 (\rho^T - 1) \sum_{i=1}^{j+1} \rho^{j+1-i} \rho^{T-i} \\
&\quad \quad \left. + \sigma_\varepsilon^2 \sum_{i=1}^{T-j-1} \rho^{T-i} \rho^{T-j-1-i} \right\} \\
&\quad + \sum_{j=T-1}^{\infty} (\alpha + \theta)^j \\
&\quad \times \left\{ [\sigma_\varepsilon^2 / (1 - \rho^2)] (\rho^T - 1)^2 \rho^{j+1} \right. \\
&\quad \quad \left. + \sigma_\varepsilon^2 (\rho^T - 1) \sum_{i=1}^T \rho^{j+1-i} \rho^{T-i} \right\}.
\end{aligned}$$

If we now let T approach ∞ , so that the second summation on the right goes to zero,

we obtain

$$\begin{aligned}
 & \sum_{j=0}^{\infty} (\alpha + \theta)^j \left\{ \left[\sigma_{\varepsilon}^2 / (1 - \rho^2) \right] \left[(\rho^T - 1)^2 \rho^{j+1} \right] \right. \\
 & \quad + (\rho^T - 1) \rho^{T-1} \rho^j \\
 & \quad \times \left[(1 - \rho^{-2(j+1)}) / (1 - \rho^{-2}) \right] \sigma_{\varepsilon}^2 \\
 & \quad + \sigma_{\varepsilon}^2 \rho^{2T-3} \rho^{-j} \\
 & \quad \times \left. \left[(1 - \rho^{-2(T-j-1)}) / (1 - \rho^{-2}) \right] \right\} \\
 & = (\rho^T - 1)^2 \left[\sigma_{\varepsilon}^2 / (1 - \rho^2) \right] \\
 & \quad \times \rho [1 - (\alpha + \theta) \rho]^{-1} \\
 & \quad + \left[\sigma_{\varepsilon}^2 / (1 - \rho^2) \right] (\rho^T - 1) \rho^{T-1} \\
 & \quad \times \left\{ [1 - (\alpha + \theta) \rho]^{-1} \right. \\
 & \quad \quad \left. - \rho^{-2} [1 - (\alpha + \theta) \rho^{-1}]^{-1} \right\} \\
 & \quad + \rho^{2T-3} \left\{ [1 - (\alpha + \theta) \rho - 1]^{-1} \right. \\
 & \quad \quad \left. - \rho^{-1} / [1 - (\alpha + \theta) \rho] \right\} \sigma_{\varepsilon}^2 \\
 & \quad \times (1 - \rho^{-2})^{-1}.
 \end{aligned}$$

Now we note that as T approaches ∞ , the second term above also goes to zero. The first term goes to $\sigma_{\varepsilon}^2 \rho / (1 - \rho^2) [1 - \rho(\alpha + \theta)]$, while the third term goes to $\rho^{-1} \sigma_{\varepsilon}^2 / (1 - \rho^{-2}) [1 - \rho(\alpha + \theta)]$. Therefore,

$$\begin{aligned}
 \text{(A5a)} \quad & \lim_{T \rightarrow \infty} [\text{Cov}(\Delta^T k_t, \Delta^T z_t)] \\
 & = \{ \sigma_{\varepsilon}^2 / [1 - \rho(\alpha + \theta)] \} \\
 & \quad \times [\rho / (1 - \rho^2) \\
 & \quad \quad - \rho^{-1} / (1 - \rho^{-2})] \\
 & = 2\sigma_{\varepsilon}^2 \rho / (1 - \rho^2) [1 - \rho(\alpha + \theta)].
 \end{aligned}$$

Next we calculate the limit as ρ approaches 1, for fixed T .

$$\begin{aligned}
 \text{(A5b)} \quad & \lim_{\rho \rightarrow 1} [\text{Cov}(\Delta^T z_t, \Delta^T k_t)] \\
 & = \sigma_{\varepsilon}^2 \sum_{j=0}^{T-2} (\alpha + \theta)^j (T - j - 1) \\
 & = \sigma_{\varepsilon}^2 [T - 1 + (\alpha + \theta) \\
 & \quad \times (T + 2) \dots (\alpha + \theta)^{T-2}] \\
 & = \sigma_{\varepsilon}^2 \{ T [1 - (\alpha + \theta)]^{-1} \\
 & \quad - [1 - (\alpha + \theta)^T] \\
 & \quad \times [1 - (\alpha + \theta)]^{-2} \} \\
 & = \sigma_{\varepsilon}^2 \{ T [1 - (\alpha + \theta)] \\
 & \quad - [1 - (\alpha + \theta)^T] \} \\
 & \quad \times [1 - (\alpha + \theta)]^{-2}.
 \end{aligned}$$

Next we turn to the computation of $\text{Var}(\Delta^T k_t)$. We have

$$\begin{aligned}
 \text{Var}(\Delta^T k_t) & = \sum_{i=0}^{\infty} \sum_{j=0}^{\infty} (\alpha + \theta)^{i+j} \\
 & \quad \times \left[(1 - \alpha)^2 \text{Cov}(\Delta^T l_{t-j}, \Delta^T l_{t-i}) \right. \\
 & \quad \left. + \text{Cov}(\Delta^T z_{t-j}, \Delta^T z_{t-i}) \right].
 \end{aligned}$$

Let

$$\begin{aligned}
 \hat{A} & = \sum_{i=0}^{\infty} \sum_{j=0}^{\infty} (\alpha + \theta)^{i+j} (1 - \alpha)^2 \\
 & \quad \times \text{Cov}(\Delta^T l_{t-j}, \Delta^T l_{t-i}).
 \end{aligned}$$

We will compute \hat{A} later. If we let ρ approach 1 for a given T , remembering that

$$\lim_{\rho \rightarrow 1} [\text{Cov}(\Delta^T z_t, \Delta^T z_{t-j-1})] = 0$$

for $t - j - 1 \leq 0$, we obtain

$$\begin{aligned} \text{Var}(\Delta^T k_t) &= \sum_{j=0}^{\infty} \sum_{i=j+1}^{T+j} (\alpha + \theta)^{i+j} \\ &\quad \times [T - (i - j)] \sigma_\varepsilon^2 \\ &\quad + \sum_{i=0}^{\infty} \sum_{j=i+1}^{T+i} (\alpha + \theta)^{i+j} \\ &\quad \times [T - (j - i)] \sigma_\varepsilon^2 \\ &\quad + \sum_{k=0}^{\infty} (\alpha + \theta)^{2k} T \sigma_\varepsilon^2 + \hat{A} \\ &= \left(2\sigma_\varepsilon^2 (\alpha + \theta) \left\{ T / [1 - (\alpha + \theta)] \right. \right. \\ &\quad \left. \left. - [1 - (\alpha + \theta)^T] / [1 - (\alpha + \theta)]^2 \right\} \right. \\ &\quad \left. + T \sigma_\varepsilon^2 [1 - (\alpha + \theta)^2]^{-1} \right) \\ &\quad \times [1 - (\alpha + \theta)^2]^{-1} + \hat{A}. \end{aligned}$$

We also compute $\text{Var}(\Delta^T k_t)$ for $\rho < 1$ as T approaches ∞ ; we have

$$\begin{aligned} \text{Var}(\Delta^T k_t) &= (1 - \alpha)^2 \sum_{i=0}^{\infty} \sum_{j=0}^{\infty} \text{Cov}(\Delta^T l_{t-j}, \Delta^T l_{t-i}) \\ &\quad \times (\alpha + \theta)^{i+j} \\ &\quad + \sum_{j=0}^{\infty} \sum_{i=0}^{\infty} \text{Cov}(\Delta^T z_{t-j}, \Delta^T z_{t-i}) \\ &\quad \times (\alpha + \theta)^{i+j}. \end{aligned}$$

Let \hat{A} again denote the first of these expressions. We shall compute it later. Next,

observe that, for $i > j$ and $T - (i - j) > 0$,

$$\begin{aligned} \text{Cov}(\Delta^T z_{t-i}, \Delta^T z_{t-j}) &= [\sigma_\varepsilon^2 / (1 - \rho^2)] \\ &\quad \times [(\rho^j - 1)^2 \rho^{i-j} \\ &\quad + \sigma_\varepsilon^2 (\rho^T - 1) \rho^{T+(i-j)-2} \\ &\quad \times (1 - \rho^{-2(i-j)}) / (1 - \rho^{-2})] \\ &\quad + \sigma_\varepsilon^2 \rho^{2T-(i-j)-2} \\ &\quad \times (1 - \rho^{-2T+2(i-j)}) / (1 - \rho^{-2}). \end{aligned}$$

If we let T approach ∞ , note that $T - (i - j) > 0$ and $T - (j - i) > 0$ for all fixed i, j . Now, break the summation for $\text{Var}(\Delta^T k_t)$ into three parts: $i > j$, $i < j$, and $i = j$. The expressions for $i > j$ and $i < j$ are symmetric, so compute twice the value for $i > j$:

$$\begin{aligned} \lim_{T \rightarrow \infty} [\text{Var}(\Delta^T k_t)] &= \lim_{T \rightarrow \infty} \left(2 \sum_{j=0}^{\infty} \sum_{i=j+1}^{\infty} (\alpha + \theta)^{i+j} \right. \\ &\quad \times [\sigma_\varepsilon^2 / (1 - \rho^2)] \\ &\quad \times \{ (\rho^T - 1)^2 \rho^{i-j} \\ &\quad + (\rho^T - 1) [\sigma_\varepsilon^2 / (1 - \rho^{-2})] \\ &\quad \times \rho^{T-2} \rho^{i-j} (1 - \rho^{-2i} \rho^{2j}) \\ &\quad + [\sigma_\varepsilon^2 / (1 - \rho^{-2})] \\ &\quad \times [\rho^{2T-2} \rho^{-i} \rho^j (1 - \rho^{-2T} \rho^{2i} \rho^{-2j})] \} \\ &\quad \left. + \sum_{j=0}^{\infty} (\alpha + \theta)^{2j} \right. \\ &\quad \times \{ [\sigma_\varepsilon^2 / (1 - \rho^2)] (\rho^T - 1)^2 \\ &\quad + [\sigma_\varepsilon^2 / (1 - \rho^{-2})] \\ &\quad \times (\rho^T - 1) \rho^{T-2} (0) \\ &\quad + [\sigma_\varepsilon^2 / (1 - \rho^{-2})] \\ &\quad \times [\rho^{2T-2} (1 - \rho^{-2T})] \} + \hat{A} \Big) \end{aligned}$$

$$\begin{aligned}
&= \lim_{T \rightarrow \infty} \left(2\sigma_\varepsilon^2 \left[\sum_{j=0}^{\infty} (\rho^T - 1)^2 (\alpha + \theta)^j \right. \right. \\
&\quad \times \rho^{-j} (\alpha + \theta)^{j+1} \rho^{j+1} \\
&\quad \times [1 - (\alpha + \theta)\rho]^{-1} (1 - \rho) \\
&\quad + \rho^{T-1} (1 - \rho^{-2})^{-1} \\
&\quad \times (\alpha + \theta)^j \rho^{T-2} \rho^{-j} \\
&\quad \times \{\rho^{j+1} (\alpha + \theta)^{j+1} \\
&\quad \times [1 - (\alpha + \theta)\rho]^{-1} \\
&\quad - \rho^{2j} (\alpha + \theta)^{j+1} \rho^{-(j+1)} \\
&\quad \times [1 - (\alpha + \theta)\rho^{-1}]^{-1}\} \\
&\quad + (1 - \rho^{-2}) \rho^{2T-2} (\alpha + \theta)^j \\
&\quad \times \rho^j \{ (\alpha + \theta)^{j+1} \rho^{-(j+1)} \\
&\quad \times [1 - (\alpha + \theta)\rho^{-1}]^{-1} \\
&\quad - \rho^{-2T} \rho^{-2j} (\alpha + \theta)^{j+1} \\
&\quad \times \rho^{j+1} [1 - (\alpha + \theta)\rho]^{-1} \} \\
&\quad + [\sigma_\varepsilon^2 (1 - \rho^{-2})^{-1} (\rho^T - 1)^2 \\
&\quad + \sigma_\varepsilon^2 (1 - \rho^{-1})^{-1} \rho^{2T-2} \\
&\quad - \sigma_\varepsilon^2 (1 - \rho^{-2})^{-1} \rho^{-2}] \\
&\quad \times [1 - (\alpha + \theta)^2]^{-1} + \hat{A} \Big) \\
&= \lim_{T \rightarrow \infty} \left(2 \{ [\sigma_\varepsilon^2 / (1 - \rho^2)] (\rho^T - 1)^2 \right. \\
&\quad \times \rho (\alpha + \theta) [1 - (\alpha + \theta)^2] \\
&\quad \times [1 - (\alpha + \theta)\rho]^{-1} \\
&\quad + (\rho^T - 1) \rho^{T-2} [\sigma_\varepsilon^2 / (1 - \rho^{-2})] \\
&\quad \times \rho (\alpha + \theta) \\
&\quad \times [1 - (\alpha + \theta)^2]^{-1} [1 - (\alpha + \theta)\rho]^{-1} \\
&\quad - [\sigma_\varepsilon^2 / (1 - \rho^{-2})] (\rho^T - 1) \\
&\quad \times \rho^{T-2} (\alpha + \theta) \rho^{-1} [1 - (\alpha + \theta)^2]^{-1} \\
&\quad \times [1 - (\alpha + \theta)\rho^{-1}]^{-1} \\
&\quad + [\sigma_\varepsilon^2 / (1 - \rho^{-2})] \rho^{2T-2} \\
&\quad \times (\alpha + \theta) \rho^{-1} [1 - (\alpha + \theta)^2]^{-1} \\
&\quad \times [1 - (\alpha + \theta)\rho^{-1}]^{-1} \\
&\quad - [\sigma_\varepsilon^2 / (1 - \rho^{-2})] (\alpha + \theta) \\
&\quad \times \rho^{-1} [1 - (\alpha + \theta)^2]^{-1} \\
&\quad \times [1 - (\alpha + \theta)\rho^{-1}]^{-1} \} \\
&\quad + [1 - (\alpha + \theta)^2]^{-1} \\
&\quad \times [\sigma_\varepsilon^2 (1 - \rho^2)^{-1} (\rho^T - 1)^2 \\
&\quad + \sigma_\varepsilon^2 (1 - \rho^{-2})^{-1} \rho^{2T-2} \\
&\quad - \sigma_\varepsilon^2 (1 - \rho^{-2})^{-1} \rho^{-2}] + \hat{A} \Big) \\
&= \lim_{T \rightarrow \infty} \left([\sigma_\varepsilon^2 / (1 - \rho^2)] [1 - (\alpha + \theta)^2]^{-1} \right. \\
&\quad \times \{ 2(\rho^T - 1)^2 [1 - \rho(\alpha + \theta)]^{-1} \\
&\quad \times \rho (\alpha + \theta) \\
&\quad - 2(\rho^T - 1) \rho^T \rho \\
&\quad \times (\alpha + \theta) [1 - (\alpha + \theta)\rho]^{-1} \\
&\quad + 2(\rho^T - 1) \rho^T (\alpha + \theta) \\
&\quad \times \rho^{-1} [1 - (\alpha + \theta)\rho^{-1}] \\
&\quad - 2\rho^{2T} (\alpha + \theta) \rho^{-1} \\
&\quad \times [1 - (\alpha + \theta)\rho^{-1}]^{-1} \\
&\quad + 2(\alpha + \theta)\rho \\
&\quad \times [1 - (\alpha + \theta)\rho]^{-1} \\
&\quad + [(\rho^T - 1)^2 - \rho^{2T} + 1] \\
&\quad + 2(1 - \rho^T) \} + \hat{A} \Big)
\end{aligned}$$

$$\begin{aligned}
&= \lim_{T \rightarrow \infty} \left(2[\sigma_\varepsilon^2 / (1 - \rho^2)] \right. \\
&\quad \times [1 - (\alpha + \theta)^2] \\
&\quad \times \left[(\rho^T - 1)^2 \rho(\alpha + \theta) \right. \\
&\quad \times [1 - (\alpha + \theta)\rho]^{-1} + (\rho^T - 1)\rho^T \\
&\quad \times \left\{ \rho^{-1} [1 - (\alpha + \theta)\rho^{-1}]^{-1} \right. \\
&\quad \quad \left. - \rho [1 - (\alpha + \theta)\rho]^{-1} \right\} (\alpha + \theta) \\
&\quad \left. + (\alpha + \theta) \left\{ \rho [1 - (\alpha + \theta)\rho]^{-1} \right. \right. \\
&\quad \quad \left. \left. - \rho^{-1} [1 - (\alpha + \theta)\rho^{-1}] \rho^{2T} \right\} \right. \\
&\quad \left. + 1 - \rho^T \right] + \hat{A} \Big).
\end{aligned}$$

Therefore,

$$\begin{aligned}
\text{(A6)} \quad &\lim_{T \rightarrow \infty} [\text{Var}(\Delta^T k_t)] \\
&= 2[\sigma_\varepsilon^2 / (1 - \rho^2)] \\
&\quad \times [1 - (\alpha + \theta)^2]^{-1} \\
&\quad \times \{ 2(\alpha + \theta)\rho \\
&\quad \quad \times [1 - (\alpha + \theta)\rho]^{-1} + 1 \} \\
&\quad + \lim_{T \rightarrow \infty} \hat{A}.
\end{aligned}$$

Finally, we need to compute \hat{A} . Since $l_t = rl_{t-1} + w_t$, the process l_t behaves like the z_t process, with r replacing ρ and with w replacing ε . Therefore, using earlier formulas for z ,

$$\begin{aligned}
\text{(A7)} \quad &\text{Cov}(\Delta^T l_{t-i}, \Delta^T l_{t-j}) \\
&= [T - (i - j)] \sigma_w^2 \quad \text{for } r \rightarrow 1
\end{aligned}$$

so that $\text{Var}(\Delta^T l_t) \rightarrow T\sigma_w^2$ and

$$\begin{aligned}
&\text{Cov}(\Delta^T l_{t-i}, \Delta^T l_{t-j}) \\
&= 2[\sigma_w^2 / (1 - r^2)] r^{i-j} \quad \text{for } T \rightarrow \infty, r < 1
\end{aligned}$$

so that $\text{Var}(\Delta^T l_t) \rightarrow 2\sigma_w^2 / (1 - r^2)$.

Now, for $r = 1$,

$$\begin{aligned}
\hat{A} &= (1 - \alpha)^2 \sum_{i=0}^{\infty} \sum_{j=0}^{\infty} \text{Cov}(\Delta^T l_{t-i}, \Delta^T l_{t-j}) \\
&\quad \times (\alpha + \theta)^{i+j} \\
&= \{ (1 - \alpha)^2 / [1 - (\alpha + \theta)^2] \} \\
&\quad \times \{ 2\sigma_w^2(\alpha + \theta) \{ T / [1 - (\alpha + \theta)] \\
&\quad \quad - [1 - (\alpha + \theta)^T] \\
&\quad \quad \times [1 - (\alpha + \theta)]^{-2} \} \\
&\quad + T\sigma_w^2 \}.
\end{aligned}$$

On the other hand, for $r < 1$,

$$\begin{aligned}
&\lim_{T \rightarrow \infty} \hat{A} \\
&= \lim_{T \rightarrow \infty} \left((1 - \alpha)^2 \right. \\
&\quad \times \sum_{i=0}^{\infty} \sum_{j=0}^{\infty} \text{Cov}(\Delta^T l_{t-i}, \Delta^T l_{t-j}) \\
&\quad \times (\alpha + \theta)^{i+j} \Big) \\
&= \lim_{T \rightarrow \infty} \left((1 - \alpha)^2 [2\sigma_w^2 / (1 - r^2)] \right. \\
&\quad \times [1 - (\alpha + \theta)^2] \\
&\quad \times \left\{ (r^T - 1)^2 r(\alpha + \theta) \right. \\
&\quad \quad \times [1 - (\alpha + \theta)r]^{-1} \\
&\quad \quad + (r^T - 1)r^T \\
&\quad \quad \times \{ r^{-1} [1 - (\alpha + \theta)r^{-1}]^{-1} \\
&\quad \quad \quad - r[1 - (\alpha + \theta)r]^{-1}(\alpha + \theta) \\
&\quad \quad \quad + (\alpha + \theta) \\
&\quad \quad \quad \times \{ r[1 - (\alpha + \theta)r]^{-1} \\
&\quad \quad \quad \quad - r^{-1} [1 - (\alpha + \theta)r^{-1}] r^{2T} \} \\
&\quad \quad \left. + 1 - r^T \right\} \Big).
\end{aligned}$$

Therefore,

$$\begin{aligned}
 (A8) \quad \lim_{T \rightarrow \infty} \hat{A} &= 2[\sigma_w^2/(1-r^2)] \\
 &\times [1-(\alpha+\theta)^2]^{-1} \\
 &\times \{2(\alpha+\theta)r \\
 &\times [1-(\alpha+\theta)r]^{-1} + 1\}.
 \end{aligned}$$

Finally,

$$\begin{aligned}
 (A9) \quad \text{Cov}(\Delta^T k_t, \Delta^T l_t) &= (1-\alpha) \\
 &\times \sum_{j=0}^{\infty} \text{Cov}(\Delta^T l_t, \Delta^T l_{t-j-1}) \\
 &\times (\alpha+\theta)^j \\
 &= (1-\alpha)\sigma_\varepsilon^2 \{T[1-(\alpha+\theta)] \\
 &\quad - [1-(\alpha+\theta)^T]\} / [1-(\alpha+\theta)]^2 \\
 &\quad \text{for } r=1.
 \end{aligned}$$

In general, for arbitrary r ,

$$\begin{aligned}
 \lim_{T \rightarrow \infty} [\text{Cov}(\Delta^T k_t, \Delta^T l_t)] &= \lim_{T \rightarrow \infty} \left\{ [(1-\alpha)\sigma_\varepsilon^2/(1-r^2)] \right. \\
 &\times \left\{ (r^T-1)^2 r [1-(\alpha+\theta)r]^{-1} \right. \\
 &\quad + (r^T-1)r^{T+1} \\
 &\quad \times \left\{ r^{-2} [1-(\alpha+\theta)r^{-1}]^{-1} \right. \\
 &\quad \quad - [1-(\alpha+\theta)r]^{-1} \} \\
 &\quad \left. - r^{2T-1} [1-(\alpha+\theta)r^{-1}]^{-1} \right. \\
 &\quad \left. + r [1-(\alpha+\theta)r]^{-1} \right\} \}.
 \end{aligned}$$

Taking the limit, for $r < 1$,

$$\begin{aligned}
 (A10) \quad \lim_{T \rightarrow \infty} [\text{Cov}(\Delta^T l_t, \Delta^T k_t)] &= [(1-\alpha)2\sigma_\varepsilon^2/(1-r^2)] \\
 &\times [1-(\alpha+\theta)r]^{-1}.
 \end{aligned}$$

Table A1 summarizes the results of this appendix that are relevant for the bias described in equation (16) of the text.

Combined cases: $r, \rho \rightarrow 1$, $T \rightarrow \infty$. We shall now use the expression in the second column, and we shall send r^2 and ρ^2 to unity at the same rate. The resulting expressions are then used in equations (16) and (17) of the text (the Landau symbol "O" refers to the order of the expression):

$$\begin{aligned}
 a_{kk} &= O\left(\frac{1}{1-\rho^2}\right) \left(\frac{2\sigma_\varepsilon^2}{1-(\alpha+\theta)^2}\right) \\
 &\times \left(\frac{2(\alpha+\theta)}{1-(\alpha+\theta)} + 1\right) \\
 &+ O\left(\frac{1}{1-r^2}\right) \left(\frac{2\sigma_w^2(1-\alpha)^2}{1-(\alpha+\theta)^2}\right) \\
 &\times \left(\frac{2(\alpha+\theta)}{1-(\alpha+\theta)} + 1\right) \\
 &= O\left(\frac{1}{1-\rho^2}\right) \left(\frac{2\sigma_\varepsilon^2}{1-(\alpha+\theta)^2}\right) \\
 &\times \left(\frac{1+(\alpha+\theta)}{1-(\alpha+\theta)}\right) \\
 &+ O\left(\frac{1}{1-r^2}\right) \left(\frac{2\sigma_w^2(1-\alpha)^2}{1-(\alpha+\theta)^2}\right) \\
 &\times \left(\frac{1+(\alpha+\theta)}{1-(\alpha+\theta)}\right) \\
 a_{kl} &= O\left(\frac{1}{1-r^2}\right) \left(\frac{2\sigma_w^2}{1-(\alpha+\theta)}\right) (1-\alpha)
 \end{aligned}$$

TABLE A1—EXPRESSIONS FOR THE a_{ij} FROM WHICH ONE MAY CALCULATE THE BIAS IN \hat{b}_k AND \hat{b}_l

Parameter	Case (a): $\lim_{r \rightarrow 1} \lim_{\rho \rightarrow 1} T$ finite	Case (b): $\rho, r < 1, \lim_{T \rightarrow \infty}$
a_{kk} :	$\frac{2\sigma_e^2(\alpha + \theta) \left(\frac{T}{1 - (\alpha + \theta)} - \frac{1 - (\alpha + \theta)^T}{[1 - (\alpha + \theta)]^2} \right) + T\sigma_e^2}{1 - (\alpha + \theta)^2}$ $+ (1 - \alpha)^2 \left[\frac{2\sigma_w^2(\alpha + \theta) \left(\frac{T}{1 - (\alpha + \theta)} - \frac{1 - (\alpha + \theta)^T}{[1 - (\alpha + \theta)]^2} \right) + T\sigma_w^2}{1 - (\alpha + \theta)^2} \right]$	$\left(\frac{2\sigma_e^2}{(1 - \rho^2)[1 - (\alpha + \theta)^2]} \right) \left(\frac{2(\alpha + \theta)\rho}{1 - (\alpha + \theta)\rho} + 1 \right)$ $+ \left(\frac{(1 - \alpha)^2 2\sigma_w^2}{(1 - r^2)[1 - (\alpha + \theta)^2]} \right) \left(\frac{2(\alpha + \theta)r}{1 - (\alpha + \theta)r} + 1 \right)$
a_{kl} :	$(1 - \alpha)\sigma_w^2 \left(\frac{T[1 - (\alpha + \theta)] - [1 - (\alpha + \theta)^T]}{[1 - (\alpha + \theta)]^2} \right)$	$2(1 - \alpha) \left(\frac{\sigma_w^2}{1 - r^2} \right) [1 - (\alpha + \theta)r]^{-1}$
a_{ll} :	$T\sigma_w^2$	$2\sigma_w^2/(1 - r^2)$
a_{ku} :	$\frac{\sigma_w^2 \{ T[1 - (\alpha + \theta)] - [1 - (\alpha + \theta)^T] \}}{[1 - (\alpha + \theta)]^2}$	$\frac{2\sigma_e^2 \rho}{(1 - \rho^2)[1 - \rho(\alpha + \theta)]}$

Note: To obtain the a_{ij} , the expressions in the first column of the table [case (a)] should be divided by T^2 ; the second column reports $\lim_{T \rightarrow \infty} T^2 a_{ij}$ for case (b).

$$a_{ll} = O\left(\frac{1}{1 - r^2}\right)(2\sigma_w^2)$$

$$a_{ku} = O\left(\frac{1}{1 - \rho^2}\right)\left(\frac{2\sigma_e^2}{1 - (\alpha + \theta)}\right).$$

Therefore, letting A_{ij} be the constant in the expression for a_{ij} ,

$$\begin{aligned} & \frac{a_{ll}a_{ku}}{a_{kk}a_{ll} - a_{kl}^2} \\ &= O\left(\frac{1}{1 - r^2}\right)(A_{ll}) O\left(\frac{1}{1 - \rho^2}\right)(A_{ku}) \\ & \times \left\{ \left[O\left(\frac{1}{1 - \rho^2}\right)(A_{kk}^1) \right. \right. \\ & \quad \left. \left. + O\left(\frac{1}{1 - r^2}\right)(A_{kk}^2) \right] \right. \\ & \times O\left(\frac{1}{1 - r^2}\right)(A_{ll}) \\ & \quad \left. - \left[O\left(\frac{1}{1 - r^2}\right) \right]^2 (A_{kl}^2) \right\}^{-1} \end{aligned}$$

where A_{kk}^1 and A_{kk}^2 are the first and second terms in the expression for a_{kk} . Now send $1 - \rho^2$ and $1 - r^2$ to 0 at the same rate, to get

$$\begin{aligned} & \frac{a_{ll}a_{ku}}{a_{kk}a_{ll} - a_{kl}^2} \\ & \rightarrow \frac{A_{ll}A_{ku}}{(A_{kk}^1 + A_{kk}^2)A_{ll} - A_{kl}^2} \\ &= \left(\frac{4\sigma_w^2\sigma_e^2}{1 - (\alpha + \theta)} \right) \\ & \times \left\{ \left[\left(\frac{2\sigma_e^2}{1 - (\alpha + \theta)^2} \right) \left(\frac{1 + (\alpha + \theta)}{1 - (\alpha + \theta)} \right) \right. \right. \\ & \quad \left. \left. + \left(\frac{2\sigma_w^2(1 - \alpha)^2}{1 - (\alpha + \theta)^2} \right) \left(\frac{1 + (\alpha + \theta)}{1 - (\alpha + \theta)} \right) \right] \right. \\ & \quad \left. \times 2\sigma_w^2 - \frac{4\sigma_w^4(1 - \alpha)^2}{[1 - (\alpha + \theta)]^2} \right\}^{-1}. \end{aligned}$$

Observing that $1 - (\alpha + \theta)^2 = [1 - (\alpha + \theta)](1 + \alpha + \theta)$ and making that substitution on the bottom line of the above expression leads to $[1 - (\alpha + \theta)]^2$ entering everywhere in the bottom of the denominator (i.e., the expression in large braces). Then, multiplying top and bottom by $[1 - (\alpha + \theta)]^2 / 4\sigma_w^2$ leaves us with

$$\frac{\sigma_\varepsilon^2 [1 - (\alpha + \theta)]}{\sigma_\varepsilon^2 + (1 - \alpha)\sigma_w^2 - (1 - \alpha)\sigma_w^2} = 1 - (\alpha + \theta).$$

Substituting this into (16) leads to (17). We now calculate the bias on \hat{b}_l :

$$\begin{aligned} & \frac{-a_{kl}a_{ku}}{a_{kk}a_{ll} - a_{kl}^2} \\ &= -O\left(\frac{1}{1 - r^2}\right)(A_{kl}) \\ & \quad \times O\left(\frac{1}{1 - \rho^2}\right)(A_{ku}) \\ & \quad \times \left\{ O\left(\frac{1}{1 - \rho^2}\right)(A_{kk}^1) \right. \\ & \quad \left. + O\left(\frac{1}{1 - r^2}\right)(A_{kk}^2) \right\} \\ & \quad \times O\left(\frac{1}{1 - r^2}\right)(A_{ll}) \\ & \quad - \left[O\left(\frac{1}{1 - r^2}\right) \right]^2 A_{kl}^2 \Big\}^{-1} \\ & \rightarrow \frac{-A_{kl}A_{ku}}{(A_{kk}^1 + A_{kk}^2)A_{ll} - A_{kl}^2} \\ &= \frac{-4\sigma_w^2\sigma_\varepsilon^2(1 - \alpha)}{[1 - (\alpha + \theta)]^2} \\ & \quad \times \left\{ \left[\left(\frac{2\sigma_\varepsilon^2}{1 - (\alpha + \theta)^2} \right) \left(\frac{1 + (\alpha + \theta)}{1 - (\alpha + \theta)} \right) \right] \right. \\ & \quad \left. + \left(\frac{2\sigma_w^2(1 - \alpha)^2}{1 - (\alpha + \theta)^2} \right) \left(\frac{1 + (\alpha + \theta)}{1 - (\alpha + \theta)} \right) \right\} \\ & \quad \times 2\sigma_w^2 - \frac{4\sigma_w^2(1 - \alpha)^2}{[1 - (\alpha + \theta)]^2} \Big\}^{-1}. \end{aligned}$$

We note that

$$\begin{aligned} & [1 - (\alpha + \theta)^2][1 - (\alpha + \theta)] \\ &= (1 + \alpha + \theta)[1 - (\alpha + \theta)]^2. \end{aligned}$$

Therefore, the above equals

$$\begin{aligned} & \frac{-4\sigma_w^2\sigma_\varepsilon^2(1 - \alpha)}{2\sigma_w^2[2\sigma_\varepsilon^2 + (1 - \alpha)^2 2\sigma_w^2] - 4\sigma_w^2(1 - \alpha)^2} \\ &= \frac{-\sigma_\varepsilon^2(1 - \alpha)}{\sigma_\varepsilon^2 + (1 - \alpha)^2\sigma_w^2 - \sigma_w^2(1 - \alpha)^2} \\ &= -(1 - \alpha). \end{aligned}$$

When substituted into (16) this leads to (18).

Appendix 3

Here, we briefly describe our analysis of the equation $K_{t+1} = sY_t + (1 - \delta)K_t$. This analysis led to the estimation reported in Tables 3 and 4. Under this hypothesis,

$$\begin{aligned} y_{t+1} &= z_{t+1} + (1 - \alpha)l_{t+1} \\ & \quad + (\alpha + \theta)\ln[sY_t + (1 - \delta)K_t] \\ &= z_{t+1} + (1 - \alpha)l_{t+1} \\ & \quad + (\alpha + \theta)\ln\{sY_t + (1 - \delta) \\ & \quad \times [sY_{t-1} + (1 - \delta)K_{t-1}]\} \\ &= z_{t+1} + (1 - \alpha)l_{t+1} \\ & \quad + (\alpha + \theta)\ln s \\ & \quad + (\alpha + \theta)\ln \left[\sum_{j=0}^{\infty} (1 - \delta)^j Y_{t-j} \right]. \end{aligned}$$

Therefore, the analogue of the equation in footnote 11 is

$$\begin{aligned}
 (A11) \quad y_{t+1} - \rho y_t &= \omega_t + (1 - \alpha)(l_{t+1} - \rho l_t) \\
 &+ (\alpha + \theta)(1 - \rho) \ln s \\
 &+ (\alpha + \theta) \left[\sum_{j=0}^{\infty} (1 - \delta)^j Y_{t-j} \right. \\
 &\quad \left. - \rho \ln \sum_{j=0}^{\infty} (1 - \delta)^j Y_{t-j-1} \right].
 \end{aligned}$$

The ω_t process was once again assumed to follow equation (4). The infinite sums in (A11) were truncated at $j = 20$. This was possible because only yearly data are used in Tables 3 and 4. Since at least about 20 years of data are needed to construct a reasonable approximation to the infinite sum of past Y 's, we could not use quarterly data, as these are available only for the postwar years (see footnote 11, however).

Research Productivity Over the Life Cycle: Evidence for Academic Scientists

By SHARON G. LEVIN AND PAULA E. STEPHAN *

The relationship between age and the publishing productivity of Ph.D. scientists is analyzed using data from the Survey of Doctorate Recipients (National Research Council) and the Science Citation Index. The longitudinal nature of the data allows for the identification of pure aging effects. In five of the six areas studied, life-cycle aging effects are present. Only in particle physics, where scientists often speak of being on a "religious quest," is there indication that scientific productivity is not investment-motivated. Vintage effects are also considered. The expectation that the latest educated are the most productive is not generally supported by the data. (JEL 022, 821, 841, 851)

Research productivity over the life cycle has become an increasingly important topic to the American scientific community as the average age of scientists affiliated with institutions of higher learning has increased.¹ A popular belief held by scientists and the lay

public alike is that science is a young person's game. Karl F. Gauss was 18 when he developed least-squares, Charles R. Darwin was 29 when he developed the concept of natural selection, Albert Einstein was 26 when he formulated the theory of relativity, and Sir Isaac Newton was 24 when he began his work on universal gravitation, calculus, and the theory of colors (Stephen Cole, 1979).

This paper examines the research productivity of scientists over the life cycle. We develop a model of scientific productivity in which scientists engage in research not only for the present value of the stream of future financial rewards associated with research, but also for the current satisfaction that research provides the scientist. The model is estimated with a unique pooled cross-section longitudinal data base² created from the National Research Council's biennial 1973-1979 *Survey of Doctorate Recipients* (SDR) for scientists at Ph.D.-granting institutions trained in six subfields of physics and earth science.

*Department of Economics, University of Missouri-St. Louis, St. Louis, MO 63121; and Policy Research Program and Department of Economics, Georgia State University, Atlanta, GA 30303, respectively. This work was supported by funds from the Alfred P. Sloan Foundation (B1983-43), the Exxon Education Foundation, and the National Science Foundation (grant no. SRS 8306947). Additional resources were provided by the Graduate School and Gerontology Program of the University of Missouri-St. Louis and the Georgia State University Research Office and College of Business Administration Research Council. All opinions expressed are those of the authors and not the granting institutions. We thank George Boyce and Sue Henn of the National Research Council for their assistance in putting together the data base. In addition to the individuals mentioned in Appendix A, we also acknowledge the help of Michael Pogodzinski, Rubin Saposnik, Frank Stafford, Lester Taylor, and members of the Emory University-Georgia State University Seminar. Graduate research assistants on the project were Robert Eisenstadt, Stacy Kottman, Jan Luytjes, and Yan Liao. Finally, we acknowledge the helpful comments of three anonymous referees.

¹Between 1968 and 1978, the proportion of young doctorates (those who received a degree in the past seven years) among science and engineering full-time faculty declined from about 43 percent to 26 percent (National Research Council, 1979 p. 26). Between 1975 and 1985, the proportion of doctoral scientists under 35 years of age engaged in teaching declined from 24 percent to 9 percent, while the proportion over 55 years of age increased from 14 percent to 24 percent (National Science Foundation, 1988 p. 44).

²The data base resides with the Data Processing Unit of the Office of Scientific and Engineering Personnel at the National Research Council (NRC). Upon request, we will provide the documentation necessary for replication. Use of the data base by researchers for purposes other than replication will likely require obtaining permission from the National Academy of Sciences and the Institute of Scientific Information, given the terms of a lease agreement signed in 1983.

The results support an investment model of scientific productivity. In five of the six areas, life-cycle aging effects are present. Only in particle physics, where scientists are often portrayed as on a "religious quest," is there any indication that scientific productivity is not investment-motivated. Assuming that demand conditions do not change markedly, these results suggest that the American scientific community over the next 10 or 15 years may not be as productive as a younger community was in the 1960's and early 1970's.

Section I presents a conceptual model of scientific productivity, incorporating both the investment and consumption motives noted above. Section II sets forth the methodology and specification used to estimate the model. Section III presents the results, and the conclusions follow in Section IV.

I. A Conceptual Framework

Two hypotheses are commonly advanced for scientists engaging in research. One focuses on research as investment-motivated, arguing that scientists engage in research because of the future financial rewards associated with the activity; the other focuses on research as consumption-motivated, downplaying the importance of financial rewards and stressing instead the scientist's fascination with the research puzzle itself. "Research is in many ways a kind of game, a puzzle-solving operation in which the solution of the puzzle is its own reward" (Warren Hagstrom, 1965 p. 16). Although the investment motive implies a decline in research productivity over the career, given the finite time horizon (Arthur Diamond, 1984), the consumption motive does not. The model set forth below incorporates both the investment and consumption motives for research.

(i) The individual chooses to allocate time between two activities, research and nonresearch, such as teaching and consulting, which produces current income.

(ii) The objective of the scientist is to allocate time in such a way as to maximize utility, U , over a career which begins at time zero, after receipt of the Ph.D., and

ends at time T , the day of retirement. Utility is a function of research output, R_t , and market goods, X_t , which cost a constant price, p . Thus, the problem is to choose s_t , the proportion of time engaged in producing research, so as to maximize

$$(1) \quad J = \int_0^T e^{-\rho t} U(R_t, X_t) dt$$

$$= \int_0^T e^{-\rho t} \ln(R_t^{\Theta_1} X_t^{\Theta_2}) dt$$

$$\Theta_1, \Theta_2 > 0.$$

We assume that T is known and, following Harl Ryder et al. (1976), also that ρ , the time-preference parameter, is zero. This particular utility function has been widely used in demand analysis (e.g., Robert Pollak and Terrence Wales, 1969; Ryder et al., 1976). Further, because of the high acceptance rates in science (Carnot Nelson and Dennis Pollock, 1970; A. Carolyn Miller and Sharon Serzan, 1984), we make the simplifying assumption that all research output is published.

(iii) Although publications do not wear out, their relevance does, as change occurs in the field. Thus, changes in the stock of publications deemed relevant, P_t , is given by

$$(2) \quad \dot{P}_t = R_t - \delta P_t$$

where δ is a depreciation rate and the dot denotes the derivative with respect to time.

(iv) Income in any time period is a function of P_t . Previous publications that are no longer valued by the field do not contribute to current income, I_t , where $I_t = \alpha(1 - s_t)P_t$ and α is the rental value of a unit of P .

(v) The change in assets, A , over time, is given by

$$(3) \quad \dot{A}_t = -pX_t + \alpha(1 - s_t)P_t + rA_t$$

where r is the interest rate.

(vi) A by-product of producing research is learning. Because most research has non-human-capital-enhancing aspects, only h

proportion of the research output that is produced at time t is incorporated into the individual's stock of knowledge. As a result, K_t , the scientist's effective knowledge (knowledge that is "up to date") equals hP_t .

(vii) Research output is produced by combining effective knowledge with time

$$(4) \quad R_t = f(s_t K_t) \\ = A_1 (s_t h P_t)^\beta \quad \beta < 1, A_1 > 0.$$

This production function has a long tradition in human capital studies (e.g., Yoram Ben-Porath, 1967; Ryder et al., 1976; Stephan, 1976; John McDowell, 1982; Diamond, 1984).

With the problem as formulated in (i)–(vii), a dynamic model is necessary. In terms of control theory, the Hamiltonian takes the form

$$(5) \quad H = \ln R_t^{\Theta_1} + \ln X_t^{\Theta_2} \\ + \lambda_{P_t} (A_1 s_t^\beta h^\beta P_t^\beta - \delta P_t) \\ + \lambda_{A_t} [-pX_t + \alpha(1-s_t)P_t + rA_t]$$

where λ_{A_t} and λ_{P_t} represent the shadow values of assets and effective publications, respectively. The necessary conditions for a maximum are to let \hat{s}_t and \hat{X}_t be control variables that maximize the objective function, subject to the conditions given by (2), (3), and (4), some initial stock of articles (coauthored, as is the custom in science, with advisors while in graduate school), and some initial stock of assets.³ Then, \hat{s}_t and \hat{X}_t maximize the Hamiltonian, and the shadow prices satisfy the equations

$$(6) \quad \dot{\lambda}_{P_t} = -\partial H / \partial P_t = -\beta \Theta_1 / P_t \\ - (\lambda_{P_t} \beta R_t) / P_t + \delta \lambda_{P_t} - \lambda_{A_t} \alpha (1-s_t)$$

$$(7) \quad \dot{\lambda}_{A_t} = -\partial H / \partial A_t = -r.$$

³There are, of course, two stages to this problem. The first stage is one of complete specialization in research and is characterized by $s_t = 1$. In the second stage, the time constraint is not binding. Here, we focus on the second stage and assume that the scientist stays in graduate school until ready to pass from stage 1 to stage 2. If, however, $\Theta_2 = 0$, the scientist never is motivated to earn income, and stage 1 persists for the duration of the career.

The optimal path is the solution to the differential equations in A , P , λ_P , and λ_A satisfying the transversality conditions that

$$(8) \quad \lambda_{P_T} P_T = 0 \quad (P_T = \text{free}, \lambda_{P_T} = 0)$$

and

$$(9) \quad \lambda_{A_T} A_T = 0 \quad (A_T = 0, \lambda_{A_T} = \text{free}).$$

Assuming that $r = 0$ in order to simplify the problem, it follows that λ_{A_t} is constant over time.

Maximizing the Hamiltonian with respect to X yields the result that market goods consumed by the individual are constant over time:

$$(10) \quad \hat{X}_t = \Theta_2 / \lambda_{A_t} p$$

where the caret denotes the optimal value. Maximizing the Hamiltonian with respect to s and substituting the value of s into (6) yields

$$(11) \quad \dot{\lambda}_{P_t} = \delta \lambda_{P_t} - \lambda_{A_t} \alpha.$$

Given the transversality conditions, this implies that

$$(12) \quad \lambda_{P_t} = (\lambda_{A_t} \alpha / \delta) [1 - e^{-\delta(T-t)}]$$

and

$$(13) \quad \hat{R}_t = A_1 [\Theta_1 E + (h\beta / \delta) \\ \times \hat{R}_t (1 - e^{-\delta(T-t)})]^\beta$$

where $E = [h\beta / (\lambda_{A_t} \alpha)] > 0$. Thus, in this model, $\hat{R}_t > 0$, even at time T , the date of retirement, when $\hat{R}_T = A_1 [\Theta_1 E]^\beta$.

Although there is no known solution for equation (13), two propositions can be derived.

PROPOSITION 1: *Research activity is greater, the greater is the taste for research, Θ_1 :*

$$(14) \quad \frac{\partial \hat{R}_t}{\partial \Theta_1} = \frac{\beta \hat{R}_t E}{\Theta_1 E + X} > 0 \quad \text{for } t < T$$

where $X = (h\beta/\delta)R_t(1 - \beta)(1 - e^{-\delta(T-t)}) > 0$ for all $t < T$ and $X = 0$ for $t = T$.

The sociology-of-science literature makes the argument that this taste for research is learned in graduate school. Moreover, interviews with scientists suggest that this taste is field-dependent, with scientists in some fields placing greater value on the satisfaction derived from engaging in research than do scientists in other fields.

PROPOSITION 2: *Research activity declines over the life cycle:*

$$(15) \quad \dot{R}_t = \frac{(-\beta^2 \hat{R}^2 h) e^{-\delta(T-t)}}{\Theta_1 E + X} < 0$$

for $t < T$.

Furthermore, although it is not possible to prove, simulations of the model support the concept that larger values of Θ_1 , the taste for research, generate flatter research profiles. This has some intuitive appeal. Early in the career, the strong investment incentive for research complements a scientist's puzzle-solving urge, but as the scientist ages and the present value of the investment benefit declines, the scientist must supplement the investment component to meet the puzzle-solving need. Clearly, this is more important the larger is Θ_1 .⁴

⁴Two special cases in which a utility parameter is zero are also of interest. First, when $\Theta_1 = 0$ and the scientist derives no satisfaction from engaging in research, the path of R_t is the same as the path in a simplified Ben-Porath income-maximizing model. In this case, $R_T = 0$, and the simulations suggest that the R_t profile is steeper than when $\Theta_1 > 0$. Second, when $\Theta_2 = 0$ and market goods provide no satisfaction, the scientist lacks the motivation to earn income and remains in the stage of complete specialization throughout the career (see footnote 3). In this situation, $s_t = 1$, and research is constrained only by the amount of effective knowledge available to the scientist. Thus,

$$R_t = A_1(hP_t)^\beta \quad \text{and} \quad \dot{R}_t = \beta R_t/P_t[R_t - \delta P_t].$$

It follows in this case that, as long as $R_t > \delta P_t$, research increases with career age. Simulations suggest that $R_t > \delta P_t$ for a period longer than a normal career for reasonable values of P_0 , A_1 , β , and h .

II. Methodology

Research productivity over the life cycle has received little attention in the economics literature, although there have been several related studies in other disciplines (e.g., Harvey Lehman, 1953; Paul Allison and John Stewart, 1974; Alan Bayer and Jeffrey Dutton, 1977; Harriet Zuckerman, 1977; Stephen Cole, 1979; Allison et al., 1982; Diamond, 1986). To date, the empirical evidence on the life-cycle effect is weak and largely inconclusive, because most studies use cross-sectional data. Since scientists of different ages come from different cohorts in a cross-sectional study, aging effects are confounded with cohort effects.

One type of cohort effect is associated with change in the knowledge base of the scientist's field. Because of what Jacob Mincer (1974 p. 21) calls the "secular progress of knowledge," there is a general presumption in science that the latest educated are the best educated. We incorporate this concept by making the depreciation rate in the model (δ) vintage-dependent, so that successively later cohorts face lower and lower depreciation rates as science progresses toward a more complete understanding of the "laws" governing the universe.⁵ Thus, the stock of relevant articles (2) declines more rapidly for scientists coming from earlier vintages than for scientists coming from later vintages. Since

$$(16) \quad \frac{\partial \hat{R}_t}{\partial \delta} = (\beta \hat{R}_t / \delta)^2 h \times \frac{(e^{-\delta(T-t)})(\delta(T-t) + 1) - 1}{\Theta_1 E + X} < 0$$

for all $t < T$, it follows that $\partial \hat{R}_t / \partial V > 0$, where V stands for the date of the Ph.D.⁶

⁵Clearly, this is a simplified view of how change in knowledge affects a scientist's stock of relevant publications. One might expect, for example, that the earliest articles authored by a scientist would be the first to be rendered obsolete.

⁶Previous work in human capital (Solomon Polachek, 1976; McDowell, 1982; Stephan and Levin, 1983) has examined variation in the rate at which knowledge becomes obsolete across academic fields or

Another factor that affects research productivity and varies by cohort is the state of the job market at the time the doctorate is received. The link in this instance between productivity and cohort is the strong evidence that research output is affected not only by attributes of the scientists but also by attributes of the employing institutions (J. Scott Long, 1978; Gerald Cole, 1979; Long and Robert McGinnis, 1981). Consequently, scientists graduating when appointments in the top academic sector are few and far between are expected to be less productive over their lives than are scientists who have the good fortune to leave graduate school when the prospects for employment in the top sector are good.

Finally, in addition to differences in the rate at which knowledge becomes obsolete and differences in opportunities that greet different cohorts over time, cohorts may vary in the levels of ability or motivation they bring to the fields or specialty areas they enter. Whether or not this occurs depends in part upon the desirability of other fields or professions relative to the one in question at the time the career decision is made. In recent years, this may have become a significant factor in science given the surge of interest in the high-salaried professions of business, law, and applied science. As a consequence, it is possible that these areas were able to secure a disproportionate share of the best minds from later cohorts, leaving some areas of science with a relative "brain drain."⁷

occupations and the consequences of this variation for investment over the life cycle as well as for career choice. While recognizing that rates of obsolescence vary across disciplines, here we focus on the idea that knowledge acquired during graduate school is more durable for later vintages than for earlier vintages, based on the assumption that science progresses towards "truth." Clearly, other issues may fall under the rubric of obsolescence (e.g., the distinction between anticipated obsolescence and unanticipated obsolescence and whether unanticipated change impacts relatively more on younger than on older scientists). Given our focus on aging, such issues are outside the scope of this article.

⁷See, for example, Howard Bowen and Jack Schuster (1986). In addition, in a recent interview on National Public Radio, Leon Lederman, a 1988 physics Nobel laureate, expressed concern over precisely this issue.

One way to control for vintage and these other cohort-related effects is to follow a single cohort over time. However, this approach ignores the fact that the scientific "state of the arts" and the work environment change over time. Thus, these calendar-time effects may also obscure the relationship between research productivity and age.

In this study, we develop a pooled cross-section time-series data base which permits us to control for cohort as well as for calendar time. The data base was created by matching records from the National Research Council's biennial 1973–1979 *Survey of Doctorate Recipients* (SDR) with publishing information from the *Science Citation Index* (SCI) prepared by the Institute of Scientific Information (ISI).⁸ (Details are provided in Appendix A). Four measures of research output were created. PUB1 measures straight publication counts occurring over a two-year period. PUB2 adjusts these counts for coauthorship. PUB3 uses Eugene Garfield's (1976) impact factor (ISI) to adjust for journal quality, while PUB4 adjusts the straight counts for both coauthorship and quality.

Although the data base was initially assembled for scientists trained in biochemistry, earth science, physics, and plant and animal physiology, the econometric investigation focused on six areas: solid-state/condensed-matter physics, particle physics, atomic and molecular physics, oceanography, geophysics, and geology.⁹ Subfield analyses were conducted because publishing patterns vary significantly across fields and subfields and the identification of vintage effects is feasible only at the subfield or specialty level. For each subfield, a case study identified vintage as well as other cohort effects (see Appendix A).

⁸Although the SDR is the largest and most comprehensive longitudinal study of scientists in the United States, it could not be used in previous studies of scientific productivity, because it did not contain measures of scientific productivity.

⁹Resource constraints and issues of confidentiality prevented us from studying other subfields or including women in the study.

The empirical analysis focuses on the research productivity of scientists employed full-time at prestigious doctoral-granting departments in their fields, for it is within this sector that the vast majority of research, at least in terms of journal publications, is produced. Thus, it was necessary to make a correction for nonrandom sample selection (James Heckman, 1979; Randall Olsen, 1980). Without this correction, life-cycle aging effects would be biased upward toward zero, since age and ability (which cannot be measured) are likely to be positively correlated in the selected sample, given that elite universities tend to hire relatively many young professors but retain only the best. Before pooling the data from each survey, we correct for this bias by estimating for each of the survey years an ordinary least-squares (OLS) regression predicting the likelihood that a scientist is employed in the selected sector and calculating Olsen's (1980) selectivity-bias correction variable. Included in each regression, among the other variables discussed in Appendix B, are categorical variables to capture the differences in job-market conditions experienced by Ph.D. cohorts.¹⁰

The model we wish to estimate takes the general form

$$(17) \quad R_{it} = f(\text{AGE}, V, T, X, S, u)$$

where R is a measure of publishing productivity of scientist i at time t , V is vintage, T is the calendar year, X is a vector of other explanatory variables suggested by the conceptual model, S is the sample-selection correction variable, and u is a stochastic

error term. The estimation strategy chosen addresses three issues: the identification of aging effects given that age, vintage, and calendar time are nearly perfectly correlated,¹¹ the presence of a limited dependent variable, and the presence of unmeasurable individual-specific fixed effects.

First, if scientists enter the labor force at the same age (APhD) and work continuously, then the calendar year (T) equals age minus APhD plus the year of doctorate, V . Because of this linear dependence ($T = \text{AGE} - \text{APhD} + V$), the effects of age, vintage, and calendar time on research productivity cannot be identified separately (William Johnson, 1980). One solution "is to assume non-linearity in the vintage effects" (Johnson, 1980 p. 401). Alternatively, identification is possible if at least one of the three variables "can be eliminated in favor of the underlying theoretical concepts" (Willard Rodgers, 1982 p. 783). Here the two solutions are merged. Following Johnson (1980), Ph.D. cohorts are grouped into intervals represented by categorical variables. The vintage effects are then modeled as a step function with each step corresponding to an interval. Rather than use arbitrary, five-year intervals as does Johnson, however, we used the case studies to identify Ph.D. classes which received a relatively homogeneous knowledge base in graduate school and thus shared a common likelihood of experiencing knowledge-obsolescence when change occurred in their field.¹²

¹¹The three effects are not perfectly correlated here, since scientists do not obtain the doctorate and enter the labor force at the same age.

¹²This required ascertaining when major changes in theory or technique occurred in the knowledge base of each subfield. Thus, if the case study for the subfield suggested that a major change occurred in 1949, another in 1955, and the last in 1967, we would group scientists in this field into four intervals and construct corresponding categorical variables: V_1 set equal to 1 if the degree was awarded after 1967, 0 otherwise; V_2 set equal to 1 if the degree was awarded between 1956 and 1967, 0 otherwise; V_3 set equal to 1 if the degree was awarded between 1950 and 1955, 0 otherwise. V_4 , the excluded (comparison) group would include those scientists educated prior to 1950. In terms of the latest-educated-are-best-educated framework, the step function should rise with each successively later vintage.

¹⁰To make this model tractable (see discussion on multiple criteria for selectivity in G. S. Maddala [1983 pp. 278–83]), we make the following assumptions. First, Ph.D. scientists desire the best academic jobs (see, e.g., R. A. Alpher et al., 1979; Beverly Porter, 1979a,b), and within academia, for the most part, mobility is downwards from the more prestigious to the less prestigious institutions. Thus, to be in the selected sample, individuals must have been chosen by these elite institutions and must have met the unwritten standards for continued employment, standards which are expected to tighten or loosen according to the state of the academic job market. Additional details concerning estimation are presented in Appendix B.

A second issue is the presence of a limited dependent variable, since some scientists in the SDR do not publish, or, at least, in certain years do not publish. Consequently, research productivity is truncated at zero, and OLS estimation would result in biased and inconsistent parameter estimates. Thus, we use the maximum-likelihood Tobit (James Tobin, 1958) procedure to estimate the parameters of the research-productivity model.

Finally, individual-specific unmeasurable effects are also an issue. It is well known that some scientists are extremely productive, while others are not. One reason for this is that some scientists possess a particular talent for research, a unique combination of creativity and motivation, which others do not possess (Mary Fox, 1983). Although this special talent may be randomly distributed and uncorrelated with age and vintage in the population of all scientists, this is unlikely in the censored samples considered here.¹³ Thus, we chose a fixed-effects estimator, rather than a random-effects (variance-components) estimator, because we expect that the unmeasurable individual-specific effects are correlated with other determinants of publishing productivity, and as a result, the variance-components estimator would be biased and inconsistent (George Judge et al., 1980).

Conceptually, this model can be estimated by including $N-1$ dummies for the individual-specific effects and $T-1$ dummies for the calendar-time effects in a Tobit specification. Inclusion of these fixed effects, however, complicates the analysis in three ways. First is the necessity that there be at least two observations per scientist in order to include the individual-specific dummies.¹⁴ Thus, in assembling the field

samples, only those scientists who were in the selected sector more than once were included.¹⁵ We refer to this as sample one in the findings reported below. A second issue that arises in the Tobit specification is that it is not possible to estimate an individual-specific fixed effect for a scientist who never published over the period surveyed. Consequently, a few additional cases were dropped from the analysis, and sample two was formed. (Note, however, that sample two still contains scientists who did not publish in some periods; thus, there remain numerous cases in which the dependent variable is truncated at zero.) Finally, because vintage itself is an individual-specific fixed effect, it proved impossible to obtain an estimate of its effect separate from the other unmeasurable individual-specific fixed effects in the model.¹⁶

Because of these complications, we chose to estimate two models using Tobit. Model A estimates the life-cycle publishing-productivity relationship for scientists in the elite sector and includes vintage dummy

ing-productivity model in each field does not differ for the two groups of scientists, the excluded and included groups, does not lead to a rejection of the null hypothesis.

¹³Note that we do not have a balanced design; scientists may be in the selected sample two, three, or four times. Although an unbalanced design necessitates an adjustment in estimating variance components (Mark Bils, 1985 p. 685), no adjustment is needed in the fixed-effects specification used here.

¹⁴Heckman and Thomas Macurdy (1980 p. 56) suggest that it would be possible to retrieve separate estimates for the vintage effects indirectly, after controlling for all the individual fixed effects, by regressing the estimated fixed effects obtained in model B on vintage. Our attempt to do so failed, however, because we have too few observations per individual. It also is not possible to obtain separate estimates for the vintage effects directly while controlling for the individual-specific effects in model B by dropping the time-period dummies. Since the vintage of the scientist does not change over time, no vintage estimate can be obtained when individual dummies for the fixed effects are included in the model. Finally, we note that Jerry Hausman and William Taylor (1981) suggest an alternative instrumental-variables technique by which it might be possible to estimate both the time-varying and time-invariant determinants of publishing productivity while controlling for the individual fixed effects. Given the time limitations of our data and our focus on aging, not vintage, we did not use their approach.

¹³For example, this latent, unobservable variable may be correlated with such determinants of publishing productivity as whether the scientist is employed at a Ph.D.-granting institution (i.e., the sample selection variable) or whether the scientist has garnered research support or reputational and positional prestige.

¹⁴Excluding cases of scientists who were in the selected sector only once raises again the possibility of sample selectivity bias. As discussed in Appendix B, a test of the conjecture that the structure of the publish-

variables in addition to the calendar-time dummies and the model's other parameters: age (AGE) and proxies (discussed in Appendix B) for the scientist's research environment (REPRANK), research effort (TEACH/ADMIN), research support (FEDSUP), and previous productivity (SALARY):¹⁷

$$(18) \quad R_{it} = c_1 + c_2 \text{AGE} + c_3 \text{REPRANK} \\ + c_4 \text{TEACH/ADMIN} \\ + c_5 \text{FEDSUP} + c_6 \text{SALARY} \\ + c_7 S_{it} + c_8 T_2 + c_9 T_3 \\ + c_{10} T_4 + c_g V_g + e_{it}$$

where T_2 , T_3 , and T_4 are the calendar-time dummies and V_g ($g = 1, 2, \dots, G$) are categorical variables from each case study, denoting different vintages of human capital. Since we did not control for the unmeasurable individual-specific fixed effects in this model, the inferences drawn about vintage effects must be viewed with caution. Model A is estimated using both samples one and two. (Because sample two is slightly smaller, in some cases the vintage categories had to be recombined.) The resulting estimates are referred to as A-1 and A-2 below.

Model B provides for a consistent estimate of the pure aging effect by including dummy variables to control for differences in the mean level of publishing productivity attributable to unmeasurables such as talent or motivation.¹⁸ This is done by dropping

the vintage variables from model A and including instead the individual-specific dummy variables, D_{i-1} , which capture all possible fixed individual-specific effects:¹⁹

$$(19) \quad R_{it} = c_1 + c_2 \text{AGE} + c_3 \text{REPRANK} \\ + c_4 \text{TEACH/ADMIN} \\ + c_5 \text{FEDSUP} + c_6 \text{SALARY} \\ + c_7 S_{it} + c_8 T_2 + c_9 T_3 \\ + c_{10} T_4 + c_{i-1} D_{i-1} + e_{it}$$

By comparing the restricted model A estimated using sample two (A-2) with the less-restricted model B, also estimated using sample two, we can test for the statistical significance of these additional, individual fixed effects and the robustness of the life-cycle effects observed in model A.

III. Findings

Space precludes the presentation of the econometric findings for all four output measures and for all six subfields. Instead, we illustrate our results focusing only on the parameter estimates for age, vintage, and calendar-time effects for one output measure, PUB1, the two-year count of journal publications.²⁰ The complete findings for all

would be likely to reflect differences in productivity between older and younger scientists, rather than differences in productivity as the average scientist aged (i.e., the pure aging effect), since the "between" variation in publishing productivity is much larger than the "within" variation.

¹⁹In estimating model B, care had to be taken to avoid singularities in the data matrix because of the multiple categorical variables representing time period and individual-specific fixed effects. Thus, in some cases, the time-period categories were collapsed, and as a result, the included categorical variables must be interpreted relative to a new omitted category.

²⁰These findings control for the likelihood of non-random sample selection discussed earlier. Although the sample-selection control variable was not always statistically significant, we found supportive evidence of bias for some form of the model estimated in 24 of the 28 possible combinations of subfields (particle physics was split into two groups; see discussion of findings) and output measures.

¹⁷Note that SALARY is, in effect, a lagged variable in the estimating equation, since research productivity is measured beginning one year after the survey date. However, one cannot automatically assume the exogeneity of SALARY. Applying the Hausman (1978) specification test in model A-1, however, we found that the null hypothesis of exogeneity could not be rejected for any output measure in any field. (The quality of graduate training and the age at time of Ph.D. were used as alternative instruments for SALARY.)

¹⁸Strictly speaking, consistency is a property of large samples and would require a large T , which is not possible in most empirical work (Maddala, 1987). If one failed to control for these individual fixed effects, we suspect that the age coefficient in the pooled model

output measures are available upon request. Although the general conclusions are not particularly sensitive to the output measure used, differences for the other output measures are noted. Table 1 summarizes the findings for the physics areas investigated, and Table 2 summarizes the earth science results. Appendix B and Tables B1 and B2 describe the variables and report descriptive statistics for each of the fields.²¹

A. Physics

Three areas in physics are investigated: solid-state/condensed-matter physics, particle physics, and atomic and molecular physics. In layman's terms, solid-state/condensed-matter physics studies why substances have certain electrical properties, as well as other properties such as color and translucence. It is the largest subfield in physics, and research in this area is responsible for the transistor and superconductors, two of the most commercially viable developments in physics. Elementary particle physics focuses on the smallest bits of matter that are known to exist. Research in elementary particle physics looks for the laws governing the four fundamental interactions—nuclear (strong), electromagnetic, weak, and gravitational—with the final aim of unifying these interactions by finding some common origin. Abstract theorists working on unification are often depicted as involved in a "religious quest," handed them by Einstein, or, as is commonly stated in the literature, the "search for the Holy Grail." The fundamental equations which concern atomic and molecular physicists come from quantum mechanics. As a result, the equations have been known for approximately 60 years, although the solutions remain elusive. Theoretical atomic physicists continue to seek solutions to these equations.

Solid-State/Condensed-Matter Physics. Overall, the results are strong. The null hypothesis that the parameters of the model are jointly zero can be rejected at a confi-

dence level exceeding 0.99. The coefficients on the time variables in A-1 and A-2 indicate that output has increased in each successive time period (by about 2–4 articles) compared to the earliest period, 1973. More-recent vintages are more productive (by about 6–8 articles) than the earliest vintage (the omitted category), those educated prior to 1948, although the difference is only statistically significant for all measures of output for V_3 and V_4 . This is consistent with the case study's conjecture that the introduction of new experimental techniques as well as many-body theory and renormalization may have had the effect of depressing the output of the pre-1948 vintage. There is, however, little indication that publishing productivity varies significantly among later vintages. Not surprisingly, when the vintages are compressed into just three categories in A-2, there is no statistical evidence of vintage effects. The results also suggest the presence of other individual fixed effects in addition to the specified vintage effects. The likelihood-ratio test comparing model A-2 and model B indicates that the null hypothesis that there are no individual-specific unmeasurable fixed effects, after controlling for vintage, can be rejected at a level of significance exceeding 0.01.

Of particular interest to this study is the coefficient on aging. In A-1 and A-2, there is strong evidence of life-cycle effects, a decline of 0.4 articles per period. When the fixed-effects model is estimated (model B), the life-cycle effects persist. The coefficients on age and age-squared suggest a nonlinear aging effect, with publishing productivity reaching a peak at age 45. (For PUB2, the peak comes at 41, for PUB3 at 45, and for PUB4 at 40.)

Particle Physics. The prestigious sector in this area consists of scientists employed both at Ph.D.-granting institutions and at federally funded research and development centers (FFRDC's). These two groups are studied separately, since their research environments differ considerably.²²

²¹A full description of the subfield samples and descriptive statistics for the other explanatory variables are available upon request.

²²We did not consider and, in fact, had no way of modeling the possibility of endogenous sector choice in

(i) *Particle physicists at Ph.D.-granting institutions.* The overall results are strong and statistically significant. Again the null hypothesis that parameters of the model are jointly zero can be rejected. A-1 shows that productivity is significantly higher, by about 2.5 articles, in 1977 (T_3). The parameter estimates for the vintage variables imply that, compared to the group educated when field theory was in its prime (represented by the excluded vintage dummy), later vintages are less productive. This is consistent with evidence presented in the case study that those educated when field theory was important may have enjoyed an edge in particle physics. The differences, however, are only statistically significant for output measures PUB2 and PUB4, and then only between the field-theory group and the latest vintage (V_1), those receiving doctorates since 1970.

When individual fixed effects are not controlled for (model A), there is evidence of aging effects, a decline of 0.3 articles per period, much smaller, however, than was observed in solid-state physics. Model B shows that the null hypothesis that the unmeasurable individual fixed effects are jointly zero must be rejected. Moreover, once these effects are controlled for, there is no evidence to support the hypothesis that research activity declines over the life cycle. This outcome is not totally unexpected. The conceptual model implies that, when satisfaction from research is an argument in the utility function, research activity remains positive until retirement. In addition, the model suggests that the productivity profile is likely to be flatter when greater satisfaction is derived from puzzle-solving activity. Among the six groups studied, theoretical particle physicists most clearly fit this picture.

(ii) *Particle physicists at FFRDC's.* The results are fairly strong, although the null

hypothesis that the parameters of the model are jointly zero cannot be rejected in model A-2. As A-1 indicates, only in 1975 is there statistical support for the presence of time-period effects. Both estimations of model A, however, suggest that FFRDC particle physicists educated after 1957 are less productive than those educated before (about 4–10 articles less) and that the group educated after 1963 (V_1 and V_2) may be less productive than those educated between 1957 and 1963 (V_3). This is consistent with the case study's finding that the field-theory generation and those educated while field theory was still in vogue may have enjoyed an edge in particle physics.

As in the case of solid-state physics, there is evidence of a strong aging effect, a decline of 0.5 articles per period. Even after controlling for all individual-specific effects, research activity declines significantly with age. Apparently, particle physicists located at FFRDC's focus more heavily on the investment component of research than their peers at Ph.D.-granting institutions. One explanation for this is that more phenomenologists and experimentalists and fewer pure theorists are located at FFRDC's.

Atomic and Molecular Physics. Again the results are strong, although there is scant evidence of time-period effects. Output is significantly higher than the base period only for 1979 (T_4) for PUB1 and PUB3. Although the more-recent vintage is more productive than the earlier vintage, the difference is not statistically significant. This is consistent with the case study's observation that no major revolution has occurred since these scientists received their doctorates.

A statistically significant inverse relationship between age and publishing productivity is observed in A-1, (for PUB3, as well), although the confidence level is less than 0.95. This statistically significant age effect, however, does not hold up when the smaller data set of sample two is used to estimate model A. Just as in the previous fields, the null hypothesis of the absence of unmeasurable individual fixed effects is rejected. Controlling for these effects, however, as model B indicates, confirms the previous finding that productivity declines with age. (This is

particle physics. Our reading of the literature, however, and our correspondence and discussions with physicists do not lead us to believe that the choice of sector is endogenous to the model of publishing productivity in this case.

also true for PUB3). It appears (although only at a 0.90 confidence level) that output at first increases and then diminishes as the scientist ages, reaching a peak at age 39. (The peak for PUB3 is age 40).

B. Earth Science

The three areas studied are oceanography, geophysics, and geology. Oceanography relies heavily on geophysical theory and methods to investigate the oceans and lands beneath them; geophysics is the study of the earth, using the basic principles of physics; and geology focuses on how the earth was formed, its composition, history, and changes. In this study, geology includes the specialties of mineralogy, petrology, stratigraphy, sedimentation, paleontology, structural geology (tectonics), and geomorphology.

If there is one development over the past 50 years in earth science that has had the stature of a major conceptual change, it is clearly the revolutionary theory of a dynamic earth, called plate tectonics, developed in the mid-to-late 1960's. Doubt exists, however, as to whether the new plate-tectonic generation of scientists possesses a knowledge edge compared to their predecessors, particularly in geology and perhaps to a lesser extent in oceanography, where research activity often focuses on observation and classification, two activities which are thought to be unaffected by a major conceptual change.

Oceanography. The results are generally weak, and to some extent, this is undoubtedly attributable to the small sample size. The null hypothesis that the parameters of the model are jointly zero can only be rejected in model B. Time-period effects are not evident in model A, although they are present when output is adjusted for quality in PUB3 and PUB4. Compared to the earliest vintage (those receiving degrees prior to 1965), each later vintage in A-1 is, on average, less productive. (The null hypothesis of no difference must be accepted, however, when output is adjusted for coauthorship, PUB2.) Thus, it does not appear that those educated subsequent to the

plate-tectonic revolution gained a knowledge edge. The results also are not consistent with an alternative hypothesis, offered by one earth scientist, that those most likely caught up in the revolution would tend to be the most productive. The productivity differences between vintages, however, disappear when the vintage categories are compressed in A-2.

In A-1, publishing productivity is found to decline significantly with age; however, it declines by less than 0.1 article per period. (When the output measure is PUB3, the age variable is not statistically significant.) After controlling for all individual-specific fixed effects in model B, statistically significant life-cycle effects are also present. Output at first rises with age and then declines, and this decline begins very early in the career. (This is also true for PUB2, but productivity appears to decline linearly with age for PUB3 and PUB4).

Geophysics. The overall results for this field are strong. In all cases, the null hypothesis that the parameters of this model are jointly zero can be rejected at confidence levels exceeding 0.99. As model A shows, there are statistically significant positive differences (of 3-4 articles) in mean publishing rates in each time period compared to the base period, 1973. With one exception, all vintage effects are negative when compared to the earliest vintage, but only for the most recent vintage in the model for PUB4 is the difference statistically significant. These results do not support the latest-are-best-educated model of knowledge obsolescence. If anything, they suggest that the plate-tectonic generation has failed to keep pace with its predecessors.

Once again, there is evidence of an inverse relationship between publishing productivity and age (a decline of about 0.5 articles per period in A-1), and the results do not change appreciably in A-2. Furthermore, these life-cycle effects persist in model B. Output peaks quite late in the career, at age 59, and then declines. (The peak is 55 for PUB2, 58 for PUB3, and 53 for PUB4).

Geology. The empirical results are again generally strong in terms of the overall significance of the models. There does not,

however, appear to be a systematic pattern of differences over time in the mean level of publishing productivity, and, although the later vintages appear to be more productive than the earliest vintage, the differences are statistically significant only in A-2. This is not surprising. Geology is largely an observational field where vintage may be of little importance. As one author suggests (John Law, 1980 p. 160), "there is something about subjects such as geology which permits a conceptual pluralism that is relatively rare in physics or chemistry." Thus, even in the face of major revolutions in thought and practice, research may proceed in the usual manner.

Model A does not indicate the presence of aging effects. After controlling for all individual fixed effects in model B, however, aging effects do appear (a decline of 0.4 articles per period), although the coefficient is only significant at the 10-percent level.

IV. Conclusions

The major finding of this study is that, with the exception of particle physicists employed in Ph.D.-granting departments, life-cycle effects are present in a fully specified model of publishing productivity which, among other things, controls for individual fixed effects such as motivation and ability. Stated differently, there is evidence that, on average, scientists become less productive as they age. The aging effect that is found is attributed to age per se and not to the possibility that, for some reason, older scientists in the sample have different attributes, values, or access to resources than younger members of the sample. Hence, research activity over the life cycle appears to be investment-motivated.

The results, although tentative, also suggest that, for the most part, vintage matters, but not in the way predicted from a latest-educated-are-best-educated point of view. With the possible exception of geology, more recent vintages are never found to be significantly more productive than earlier vintages. Perhaps, in retrospect, this outcome is not all that surprising, given that the case studies suggest that, in at least some of the

fields, more-recent vintages may not have had a knowledge edge. For example, the physics case study suggests that atomic and molecular physics has not experienced dramatic changes in thought or technique during the past 40 years since the upheaval brought about by the quantum revolution. In other fields, such as solid-state/condensed-matter physics, although numerous developments could have produced vintage effects, it appears that there is a role for what one physicist called "ditch diggers," scientists who remain active by producing "backwater" research. Furthermore, the case study also suggests that, in particle physics, some later vintages may have enjoyed less of a knowledge edge because they were trained in concepts that subsequently proved to be dead ends. In addition, the earth-science case study raises doubt as to whether the plate-tectonic revolution as well as advances in computer technology would render older scientists coming from earlier vintages less productive.

There is, however, another more speculative explanation as to why the latest vintages, with the possible exception of geology, proved to be no more productive than the earlier vintages. During the 1960's and very early 1970's science grew very rapidly. It is possible that scientists obtaining doctorates during this period of rapid expansion may have been, on average, not as talented or motivated as scientists coming from earlier cohorts, which represent a smaller, more elite portion of the population. As a result, even if these scientists have a knowledge edge, a "talent deficit" may make them no more productive than their peers.

In the econometric model specified, a sample-selection variable was introduced to control for market conditions affecting employment location, and vintage dummies were introduced to capture knowledge-obsolescence effects. Since no variable directly controlled for the average ability or motivation of the cohort, it is possible that the vintage dummies reflect not only change in knowledge but also change in the average ability or motivation of the cohort. This would explain why the most-recent vintages

are never found to be more productive, with the possible exception of geology. The results also suggest that this ability/motivation argument might be extended well into the 1970's and 1980's, long after the growth in science peaked, perhaps because the best students were attracted into careers in law, business, and medicine. Bowen and Schuster (1986 pp. 224-6) document a marked shift away from the academic sector in the career choices of such highly talented members of the population as Rhodes scholars and Phi Beta Kappa members over the period 1965-1979.

Together, the aging and vintage results suggest that, during the next 10 or 15 years, the American scientific community will not be as productive as it was in the 1960's and early 1970's, assuming market conditions do not change dramatically. Not only will the community be older, but over time the community will become increasingly dominated by scientists who did not come from particularly productive cohorts.

APPENDIX A—DATA

Previous research on the relationship between age and scientific performance has been hampered by the lack of a comprehensive data base containing measures of productivity for scientists. We have assembled such a data base by using a computer algorithm to link the journal-publication data contained in the *Science Citation Index* (SCI) with the biennial *Survey of Doctorate Recipients* (SDR).

The number of journal articles is chosen as the measure of productivity, since it is generally recognized that the journal literature is the major outlet for recording scientific advances in many disciplines (Henry Menard, 1971). Publication counts are established for scientists trained, as designated in either the SDR or the *Survey of Earned Doctorates* as biochemists, earth scientists, physicists (excluding astronomers and astrophysicists), or physiologists by a computer algorithm using the source and corporate address files of the SCI. We count the flow of publications for a period of two years, beginning one year after the survey date of the scientist (1973, 1975, 1977, or 1979), given evidence on the length of the lag between the inception of the research project and the time at which the resulting output is likely to appear (Nelson and Pollock, 1970).

The magnitude of this project can be seen by considering the size of the two files that were linked. On the SDR side, even though we restricted the analysis to scientists in just four fields, including all sectors of employment there were 18,909 records for the 1973-1979 interview period. On the SCI side, over the

period 1974-1981, there were in excess of 9.6 million entries in the *Source Index*. Because of the confidential nature of the SDR, all work linking the data bases was performed by the Data Processing Unit at the *National Research Council* (NRC). The initial match procedure used was a variant of that developed by George Boyce at NRC for the study conducted by Lyle Jones et al. (1982). The match queued on last name, first name, middle initial (if present), state/country, and zip code. The completed match is approximately 95 percent accurate (Stephan and Levin, 1988).

A large part of this research involved the development of case studies to specify the market-determined dummy variables for cohort effects used in the selection equation, as well as the vintage dummy variables included in model A. These case studies are available upon request. Information for the case studies was gathered from various publications, including those produced by outside observers of the field such as historians and sociologists of science, personal interviews, and a mail survey. In interviews and in the questionnaire, scientists were asked to identify changes occurring in their specialty, either in theory or in research techniques, that could have negative effects on the productivity of persons trained before the innovation occurred. Two physicists, Steve Manson and Steve Sigur from Atlanta, gave particularly freely of their time, as did Spencer Weart of the American Institute of Physics (AIP). In addition, Beverly Porter of AIP was extremely helpful in identifying cohort effects. In physics, the survey was sent to 63 scientists, many of whom were members of the Brinkman Panels, established by NRC to review the state of physics in the 1980's. Of the 63, 26 physicists replied, either by completing the survey or by writing a letter. Of the 38 surveys mailed to geoscientists, eight returns were particularly useful. The late Bill Menard, a distinguished oceanographer, and William Glen, editor of *Eos*, were especially helpful.

APPENDIX B—ESTIMATION

The Olsen technique was used to obtain the sample-selection correction variable, SVAR. For each survey year, the probability of sample inclusion in a Ph.D.-granting department was estimated by ordinary least squares using the following regressors: the quality of graduate training, age, age-squared, whether the respondent was born in the South, whether the respondent was born in the non-South or Canada, the age at time of Ph.D., market-determined cohort effects (dummy variables), and interactions between the quality of graduate training and the market cohort effects. All of these variables, with the exception of categorical variables representing the quality of graduate training and dummy variables for the cohort effects are taken from the National Research Council's *Survey of Doctorate Recipients* (SDR). Data on the rankings of graduate departments over time (Hayward Keniston, 1959; Allan Cartter 1966; Kenneth Roose and Charles Anderson, 1970; Jones et al., 1982) are used to sort the Ph.D.-granting institutions into five categories, ranging from departments that were not ranked to departments

TABLE B1—DESCRIPTIVE STATISTICS FOR SUBFIELDS OF PHYSICS

Variable	Mean	SD	N
Solid-state physicists:			
PUB1 = total count of publications for two-year period	3.830	4.086	182
AGE = age	41.533	7.093	182

V_1 = 1 if year of Ph.D. > 1963; 0 otherwise	0.416	0.496	89
V_2 = 1 if year of Ph.D. ≤ 1963; 0 otherwise	0.584	0.496	89

that were in the top five. These intermediate results are available upon request.

Our commitment to a fixed-effects specification necessitated restricting the analysis to scientists employed in the top sector more than once. This meant excluding approximately 17 percent of the observations. The predominant reason that scientists appeared in the top sector only once was because they were surveyed (or responded) only once. To investigate the possibility

that other scientists systematically self-selected out of the top sector, following Daniel Hamermesh (1987), we tested whether the structure of model A differed between those who were in the top sector only once and those who were in more than once. On the basis of likelihood-ratio tests, the null hypothesis of no difference in the basic structure of model A for the two groups could not be rejected at the 95-percent level for all measures of output in all subfields.

TABLE B2—DESCRIPTIVE STATISTICS FOR SUBFIELDS OF EARTH SCIENCE

Variable	Mean	SD	N
Oceanographers:

V_6 = 1 if year of Ph.D. < 1945; 0 otherwise	0.145	0.354	172

In addition to age, vintage, the correction for sample-selectivity bias (SVAR), and time-period dummy variables, model A also controls for REPRANK, SALARY, ADMIN/TEACH, and FEDSUP. REPRANK is taken from Jones et al. (1982), while the other variables are derived from data in the SDR. REPRANK measures the reputational rating of graduate departments and is included given the abundance of evidence that productivity is positively related to department quality (Long, 1978; Long and McGinnis, 1981; Fox, 1983). Moreover, it is also highly correlated with other measures of the richness of the research environment in which the scientist works. SALARY, the scientist's adjusted (for inflation) annual salary, is related to the scientist's past productivity and hence

serves as a proxy for reputational prestige and cumulative advantage. ADMIN/TEACH captures whether the scientist devotes considerable effort to nonresearch activities. Finally, FEDSUP indicates whether the scientist presently has government research support. Although not reported in the text, the findings with respect to all control variables were generally consistent with expectations.

The preliminary analysis also considered additional explanatory variables. These included such proxies for ability as whether the individual attended a select undergraduate institution, the rating of the graduate institution attended, and proxies (dummy variables) to capture exogenous differences in publishing productivity by field because scientists may be working in fields

other than their field of training. Since in no case did it appear that these additional regressors had a marked effect on the results, they have been omitted from the findings reported here. Also considered in preliminary work was a dummy variable for tenure status and a variable for the number of years since tenure was received. Unfortunately, because there were so many cases in which the scientist failed to indicate tenure status and numerous inconsistencies between the years since tenure and the reported employment history, analysis including these variables was not pursued further.

Economic Effects of Federal Credit Programs

By WILLIAM G. GALE*

Since 1980, the federal government has directly subsidized one-third of all nonfederal borrowing. This paper presents numerical estimates of the effects of federal lending. Existing credit subsidies appear to have important effects on the allocation of credit, but little effect on aggregate investment. Efficiency costs are shown to be large (approximately 1/3 percent of GNP). Government costs exceed 50 cents per dollar of incremental targeted lending. Interactions among programs can eliminate much or all of the original gain provided by a subsidy, especially if borrowers are rationed. The paper also examines the effects of several policy reforms. (JEL 313, 321)

From 1980 to 1987, the Federal government borrowed \$1,253 billion to cover budgetary shortfalls.¹ Large and persistent fiscal deficits have generated widespread attention in academic and policy debates. Over the same period, federal lending programs extended \$1,208 billion of net credit, while new federal and federally assisted lending exceeded \$4 trillion. Since 1980, the federal government has subsidized, guaranteed, or directly extended more than one-third of all borrowing by nonfederal sectors. However, despite the potential importance of federal credit activity, there exist few systematic analyses of the effects and appropriate role of the government as a lender. Barry Bosworth et al. (1987) provide a comprehensive discussion of issues and characteristics of lending programs but provide little formal analysis. Gregory Mankiw

(1986), David de Meza and David Webb (1987, 1988), Gale (1989, 1990b), and Bruce Smith and Michael Stutzer, (1989) provide theoretical models of the effects of credit subsidies in markets with imperfect information.² Charles Calomiris et al. (1986) analyze the empirical effects of agricultural credit policy.

The purpose of this paper is to develop a framework in which to analyze the quantitative effects of federal lending on credit allocation, economic efficiency, and related issues. The underlying model is based on Joseph Stiglitz and Andrew Weiss (1981) and posits asymmetric information between borrowers and lenders. Government interventions are modeled as part of an overall market for credit, which may be characterized by market clearing, rationing, or redlining of different borrower groups. Thus, it is possible to see how the effects of credit interventions depend upon the initial regime. In addition, the model accounts for the financing costs of federal credit, interactions among programs, and the use of alternative credit instruments.

The main contribution of this paper is to simulate the model described above to generate numerical estimates of the effects of

*Department of Economics, UCLA, Los Angeles, CA 90024-1477. This paper is based on my Ph.D. dissertation. I thank my advisor, Michael Boskin, for many helpful discussions. I have also benefitted from comments from Doug Bernheim, David Butz, Al Harberger, Frank Howland, Seonghwan Oh, Eric Rasmusen, John Riley, Russell Roberts, John Karl Scholz, John Shoven, Jonathan Skinner, Michael Waldman, and two anonymous referees, and I gratefully acknowledge financial support from the John M. Olin Foundation. I thank Lorraine Grams for expert assistance in the preparation of this paper.

¹All statistics in this paragraph are based on the data provided in Table 1, except for new federal and federally assisted lending, which is based on data provided in "Special Analysis F" of the U.S. Budget.

²Bruce Smith (1983) discusses optimal government lending with imperfect information but focuses on monetary policy rather than targeted credit subsidies. An important earlier paper on credit subsidies is Rudolph Penner and William Silber (1973).

credit programs. Principal conclusions are as follows. Existing credit subsidies raise aggregate private investment by between 0 percent and 4 percent, depending on the elasticity of the supply of funds. Crowding out depends critically on the supply elasticity but is bounded at a maximum of about 5 percent of original borrowing by nontargeted sectors. The allocational effects of lending policies depend on the size of the effective subsidy, rather than on credit volume. As a consequence, lending programs exert important effects on the allocation of funds to farmers, students, small businesses, and tax-exempt borrowers. The well-known federal mortgage-guarantee programs are estimated to have smaller net effects because of the smaller effective subsidies they provide. The allocational effects can also depend on the initial state of the market. If a target group is rationed, credit programs can exert very strong effects, by releasing the rationing constraint.

Although the underlying model allows for the possibility of welfare-improving interventions, the estimated efficiency cost of actual credit policy is high: approximately \$10–15 billion, or 1/3 percent of gross national product in 1987. These estimates are relatively insensitive to assumptions about the elasticity of supply of funds. Therefore, even if the crowding-out effects are small, the welfare loss is still sizable.

Because both new and inframarginal borrowers receive funds, credit subsidies cost the government in excess of 50 cents per dollar of *incremental* target-group investment. In addition, most direct welfare gains appear to accrue to borrowers who would have received credit without government subsidies. These subsidies represent pure windfall gains for the recipients, with no obvious corresponding societal benefits. All current programs require the existence of large external benefits to be welfare-improving. Even programs for groups that would have been excluded from private markets without federal assistance (say, students) face this requirement, because the default and subsidy costs are so large.

Because a subsidy to one target group crowds out other target groups as well as

nontargeted groups, interactions among programs can indirectly eliminate much or all of the original direct gain. In the low-supply-elasticity case examined here, up to 15 percent of the direct gains to farmers, students, and small businesses are offset by the effects of other credit programs. Interactions can be even more severe if a target group is rationed or redlined.

Two general principles emerge for policy reform. First, the effectiveness of any proposed reform depends on the structure of the original subsidy. For example, the vast majority of the cost of student-loan guarantees stems from the government's willingness to cover interest payments until the student graduates. Many policy proposals, however, focus on reducing the default rate, which would have only a minor impact on the costs of the program. Second, programs in which the government provides appropriate marginal incentives appear to be more efficient than programs that attempt to replace private credit arrangements. These results indicate that, although there is still a role for government in the more marginal sectors of the credit market, that role is more limited and somewhat different in nature than current policies would suggest.

Section I provides an overview of current federal credit activity. Section II develops the formal model. Section III specifies parameter values. Section IV presents the main results. A concluding section discusses caveats and extensions to this line of research. Appendixes A and B describe some important calculations and provide detailed references for the parameter specifications, respectively.

I. An Overview of Federal Credit Subsidies

The government supplies credit through several instruments.³ Direct loans typically offer large subsidies and are concentrated in the agricultural and rural sectors. Loan

³Detailed information concerning federal credit programs may be found in "Special Analysis F," in *Special Analyses: Budget of the U.S. Government* (any year) or in Bosworth et al. (1987).

TABLE 1—FEDERAL LENDING AND DOMESTIC CREDIT MARKETS (DOLLAR AMOUNTS IN BILLIONS)

Statistic	Fiscal Year								Total
	1980	1981	1982	1983	1984	1985	1986	1987	
Net credit advanced in nonfinancial credit markets	341.7	375.9	388.9	550.2	753.9	854.8	831.7	685.2	4,782.3
Net federal and federally assisted lending	110.2	109.9	131.8	140.2	129.9	246.7	159.9	179.5	1,208.1
Direct loans	24.2	26.1	23.4	15.3	6.3	28.0	11.2	-19.0	115.5
Guaranteed loans	31.6	28.0	20.9	34.1	20.1	21.6	34.6	60.4	251.3
GSE	24.1	32.4	43.3	37.1	53.1	60.7	83.3	107.8	441.8
Tax-exempt credit	30.3	23.4	44.2	53.7	50.4	136.4	30.8	30.3	399.5
Federal borrowing from the public	70.5	79.3	135.0	212.3	170.8	197.3	236.3	151.7	1,253.2
Federal lending as a percentage net credit	32	29	34	25	17	29	19	26	25
Federal lending as a percentage of federal borrowing	156	138	98	66	76	125	68	118	96
Federal lending as a percentage of nonfederal borrowing	41	37	52	41	22	38	27	34	34

Note: Net lending is new lending minus repayments.

guarantees assist a wide range of borrowers, particularly home-owners, small businesses, students, and exporters. Clifford Hardin and Arthur Denzau (1981) report the existence of more than 350 direct and guaranteed lending programs. Government-sponsored enterprises (GSE) aid borrowers in housing, agricultural, and student loan markets, primarily through the operation of secondary markets.⁴ Tax-exempt status allows state and local governments to borrow at reduced cost and to operate their own credit programs by passing on the interest savings to preferred borrowers. Effective subsidy rates, default rates, and credit volume vary greatly across sectors and programs and are discussed in detail below.

Credit policies are typically justified in terms of preexisting distortions (e.g., student loans), distributional concerns (farm loans), or externalities (small businesses). Credit subsidies have also been proposed as solutions to issues such as energy development and the maintenance of international

competitiveness. In addition, emergency loan guarantees have assisted Chrysler, Lockheed, and New York City in recent years.⁵

As shown in Table 1, lending programs account for an important share of credit advanced in domestic capital markets. The volume of net federal lending has grown at approximately the same rate as overall credit in the 1980's and has exceeded \$100 billion in every year since 1980. In a typical year, federal lending accounts for one-fourth of all net credit advanced and one-third of all nonfederal borrowing. Since 1980, the amount of net federal and federally assisted lending is approximately the same as the amount of federal borrowing.

Extensive lending activity, per se, does not imply that credit policy imparts important effects on the economy. However, the sheer magnitude and pervasiveness of credit interventions suggest the need for further

⁴For a detailed discussion of issues concerning government-sponsored enterprises see Thomas Stanton (1988).

⁵Paul Chaney and Anjan Thakor (1985) analyze emergency guarantees. However, these should be distinguished from ongoing guarantee programs that guarantee many loans and smaller amounts per loan and that do so at the time the loan is made.

analysis. In particular, the volume of federal credit activity indicates that any formal analysis should consider the effects of subsidies on nontargeted groups and the financing of credit policy. The diversity indicates the need to model several types of lending instruments and interactions among credit programs. Finally, since many of the targeted groups appear to be the marginal borrowers in modern credit markets, analysis of both rationing and market-clearing outcomes will be relevant. The next section outlines a model with these characteristics.

II. A Model of the Credit Market⁶

The underlying model is a variant of Stiglitz and Weiss (1981) and analyzes a competitive loan market in which lenders have imperfect information about borrowers. The market consists of government and many borrowers, depositors, and financial intermediaries. All agents are risk-neutral; there is no aggregate risk. Depositors supply funds to the market according to a function $S(\rho)$, where ρ is the certain rate of return on bank deposits.

Borrowers are divided into $n+1$ groups: n target groups for credit policy and one general (nontargeted) group.⁷ Borrowers are characterized by two pieces of information: their group identity and their location within that group. Group identity is assumed to be public information and will provide a (noisy) signal of borrowers' riskiness. Location within a group refers to the riskiness of the individual's projects and is known only to the individual borrower. With these informational assumptions, lenders (including the government) can determine which groups are eligible for credit subsidies, yet still face residual uncertainty within each group.

Borrower groups are indexed by $i = 0, 1, \dots, n$ and characterized by two behavioral assumptions. First, the demand for

loans (L_i^D) is a decreasing function of the effective interest rate (r_i^*) paid by the borrower. Second, the repayment rate (ϕ_i) falls as r_i^* rises. That is, increases in effective interest rates generate adverse selection in each loan market.⁸

Financial intermediation ("banking") is subject to free entry and constant returns to scale. Since they can discern only a noisy signal of borrowers' riskiness, banks set different loan rates for each group.⁹ The expected return to the bank on a loan to target group i at rate r_i is

$$\rho_i = \rho_i(r_i, \phi_i, C_i)$$

where C_i (a vector) represents credit policy for target group i . Holding credit policy constant, the existence of adverse selection implies that an increase in lending rates may eventually lead to a reduction in the banks' expected return.¹⁰ This relationship is shown as the ρ_j curve in Figure 1.

⁸These results can easily be derived from primitive assumptions on information, endowments, technology, and preferences. For example, Gale (1990b) uses the information structure above and assumes that an investor in group I with riskiness j has no endowment, must borrow to invest, has an available project of unit size which succeeds with probability $p_I(j)$, pays $R_I(j)$ if successful, and pays 0 otherwise. For any two borrowers j_1 and j_2 in group I , if $R_I(j_1) > R_I(j_2)$ then $p_I(j_1) < p_I(j_2)$. This implies that

$$L_I^D(r_I^*) = \int_0^{j_I^*(r_I^*)} f_I(j) dj$$

and

$$\phi_I(r_I^*) = \left[\int_0^{j_I^*(r_I^*)} p_I(j) f_I(j) dj \right] / F_I(j_I^*(r_I^*))$$

where j_I^* is the marginal borrower in group j (i.e., j_I^* is defined by $R_I(j_I^*) = r_I^*$) and where f and F represent the density and distribution of j , respectively. Similar specifications can be used to generate the supply curve. Thus, the underlying supply and demand functions are structural (i.e., invariant with respect to credit policy).

⁹Allowing banks to set an interest and collateral requirement for each group would not change the results as long as the collateral is incomplete (i.e., as long as banks prefer that borrowers repay rather than default).

¹⁰More generally, adverse selection implies that ρ need not be monotonic in r (see Stiglitz and Weiss, 1981).

⁶This section provides a brief overview of the underlying theoretical model, which is derived rigorously in Gale (1990b).

⁷Additional nontargeted groups can be incorporated as well.

FIGURE 1. BANK RETURN ON GENERAL LOANS (ρ_G) AND TARGET-GROUP LOANS (ρ_j)

As shown in Figure 1, the maximum bank return on general loans (ρ_G^*) is assumed to be at least as great as that available on target group loans: $\rho_G^* \geq \rho_j^*$, $j = 1, \dots, n$.¹¹ This assumption will prove necessary and sufficient to imply that situations exist in which the general market clears while target groups are rationed or redlined.

The government may assist target groups through subsidized lending, loan guarantees, or tax-exempt status. The subsidies reduce the effective interest rate and raise the expected bank return to target-group lending indirectly through $\phi_i(r_i^*)$ and in some cases directly (e.g., loan guarantees). The government borrows to fund its credit programs and pays its creditors with program revenue first and lump-sum taxes on depositors. These assumptions force explicit recognition of the costs of the programs. The government has the same information and borrowing costs as banks.

The model is competitive in that there are many agents and entry is free. There is, however, one important departure from the standard competitive framework: in addition to caring about aggregate demand,

¹¹Figure 1 also shows $\rho_G(r) > \rho_j(r) \forall j, r$. This assumption is not necessary for any of the results, but simplifies the figure.

banks also care about the identity of the borrowers demanding loans. Thus, an important concept will be effective demand—demand for loans that banks are willing to supply. Effective demand for borrower group i is given by

$$L_i = \begin{cases} L_i^D & \text{if } \hat{\rho} < \rho_i^*(r_i^*) \\ 0 & \text{if } \hat{\rho} > \rho_i^*(r_i^*) \end{cases}$$

where $\hat{\rho}$ is the equilibrium value of ρ . For example, in Figure 1, if the equilibrium cost of funds is greater than ρ_j^* , banks will not consider making loans to group j , since such loans would generate negative expected profits. If $\hat{\rho} = \rho_i^*$, L_i is determined as a residual, after other credit demands have been met, such that $0 \leq L_i \leq L_i^D(r_i^*)$. These considerations imply that aggregate effective demand, shown in Figure 2 (for $n = 1$), is a step function.¹² In equilibrium, the market for target-group loans may be characterized by market clearing (S_3), rationing (S_2), or redlining (S_1), depending on the relative magnitudes of supply and effective demand.¹³

Equilibrium is characterized by two economic conditions. First, banks' expected returns to lending are equalized across all groups that receive loans and are equal to the cost of funds (zero profits):

$$(1) \quad \hat{\rho} = \rho_i \quad \text{if } \rho_i^* \geq \hat{\rho}.$$

Second, the sum of private and public demands equals the supply of funds:

$$(2) \quad S(\rho) = \sum_{i=0}^n [L_i + G_i]$$

where G_i is government borrowing to fund programs for group i . A third set of equations shows that credit subsidies drive a

¹²See John Riley (1987) for an independent derivation of this demand curve.

¹³A supply curve intersecting the horizontal demand strip to the left of S_1 would represent rationing of general borrowers and redlining of target borrowers. This case is not considered.

FIGURE 2. AGGREGATE EFFECTIVE DEMAND FOR $n=1$

wedge between effective interest rates and loan rates:

$$(3) \quad r_i^* = g(r_i, C_i) \quad i = 0, 1, \dots, n.$$

The simulations employ the following supply and demand functions:

$$(4) \quad S = a(\rho)^\alpha$$

$$(5) \quad L_i^D = b_i(r_i^*)^{\beta_i} \quad i = 0, 1, \dots, n$$

where α and β_i represent constant elasticities and a and b_i are constants. As shown in Appendix A, government borrowing to fund credit policy for group i is given by

$$(6) \quad G_i = L_i s_i$$

where s_i is the percentage reduction in the present discounted value of borrowers' loan payments due to federal credit subsidies.

Appendix A also shows that the relationship among ρ , r_i , and r_i^* may be reduced to a single set of equations, summarized here as¹⁴

$$(7) \quad r_i^* = f(\rho, \phi_i, C_i) \quad i = 0, 1, \dots, n.$$

¹⁴The loan rate, r_i , vanishes from the equilibrium calculation because it is determined by ρ , ϕ_i , and C_i .

The effective interest rate rises with increases in deposit rates and falls with increases in credit subsidies and the probability of repayment. Equations (2) and (4)–(7) represent the market-clearing equilibrium, with S , L_i^D , G , ρ , and r_i^* endogenous.¹⁵

If group j is rationed, equation (2) is modified to become

$$(8) \quad L_j + G_j = S - \sum_h (L_h^D + G_h)$$

where h indexes groups with $\rho_h^* > \hat{\rho}$. Lending to group j is determined as a residual. As shown in Figure 2, the equilibrium cost of funds must equal the maximum bank rate of return on group- j loans:

$$(9) \quad \hat{\rho} = \rho_j^*.$$

Equations (4)–(9) represent the rationing equilibrium.

One important characteristic of the model is that, in equilibrium, banks order borrower groups by their maximum rate of return and serve the groups sequentially. If the equilibrium cost of funds is $\hat{\rho}$, all groups j with $\rho_j^* > \hat{\rho}$ have clearing credit markets, those with $\rho_j^* = \hat{\rho}$ are rationed,¹⁶ and those with $\rho_j^* < \hat{\rho}$ are redlined. Because banks order the borrower groups and because $\rho_G^* > \rho_j^*$, target groups are the residual borrowers. As a consequence, if a target group is rationed, the marginal effects of changes in supply or demand fall completely on the rationed group, while general borrowers are left unaffected. An interesting implication of this result occurs when one target group is rationed and another is redlined: the burden of subsidies to the previously redlined group falls entirely on the rationed group. In this case, credit subsidies simply rearrange loans among target groups; aggregate targeted borrowing does not rise.

A second important feature of the model is that the ordering of projects by borrower returns and social returns will differ, in gen-

¹⁵Redlining equilibria are identical to market-clearing equilibria, except that the index runs over only those groups with positive loan values.

¹⁶There is an infinitesimal chance that these groups clear or are redlined, depending on the position of S_2 in Figure 2.

TABLE 2—CHARACTERIZATION OF FEDERAL CREDIT POLICIES, 1980–1987

Sector	Principal credit instrument	s	s^G	s^O	γ	δ	σ
Mortgage	loan guarantees	0.02	< 0.01	0.02	1.0	1.0	0.01
Farm	direct lending	0.25	0.00	0.25	0.0	0.0	0.00
Student	loan guarantees	0.32	0.04	0.28	1.0	1.0	0.39
Small business	loan guarantees	0.14	0.09	0.00	0.9	0.0	0.91
Tax-exempt	interest subsidy	0.19	0.00	0.19	0.0	0.0	0.00
Variable	Definition						
s	overall reduction in the present discounted value of loan payments induced by federal credit subsidies $= s^O + s^G$						
s^G	reduction in the present discounted value of loan payments induced by just the subsidized guarantee						
s^O	reduction in the present discounted value of loan payments due to other factors						
γ	proportion of principal and interest covered by the guarantee						
δ	proportion of guarantee fee paid by the borrower						
σ	subsidized portion of the guarantee fee						

Sources: See text and Appendix B.

eral. As a consequence, subsidies can raise or reduce welfare (defined as total surplus), depending on the investment response and the size of the subsidy (Gale, 1990b). Whether actual policies raise welfare is examined below.

III. Parameter Specification

The specification of federal credit programs is potentially complicated due to the large number and diversity of credit programs, as discussed in Section I. However, a sizeable percentage of both the credit volume and the subsidies inherent in credit programs is concentrated in a relatively small number of programs and sectors. In 1986, the five sets of programs listed in Table 2 accounted for 93 percent of all new credit advanced, subsidized, or guaranteed by the government, including 75 percent of direct loan obligations and 90 percent of guaranteed loans.^{17,18} The subsidies in these

programs accounted for approximately 75 percent of all subsidies extended through loan guarantees and 50 percent of subsidies extended through direct lending (excluding foreign military sales credit). In order to capture the main effects of credit interventions without needlessly complicating the analysis, the simulations focus on these programs. Table 2 specifies their underlying parameters. A brief discussion is presented here; detailed references are given in Appendix B.

The overall percentage reduction in the present discounted value of a borrower's loan payments induced by a federal subsidy is given by s and is estimated by the Office of Management and Budget.¹⁹ All target groups except mortgage borrowers receive substantial subsidies from the government. These benefits may appear in one of two forms: a subsidized fee for a loan guarantee (s^G) or "other" forms (s^O), including reduced interest payments, deferral of payments, grace periods, and longer maturities. A loan-guarantee fee is considered to be subsidized if it does not cover the expected

¹⁷These figures omit government-sponsored enterprises (GSE's) other than the Farm Credit System, which are also omitted from the simulations, in order to avoid the need to model the operation of secondary markets. However, since GSE's are concentrated in mortgage, farm, and student credit markets, the importance of credit subsidies to the five sectors listed would increase if GSE's were included.

¹⁸The programs listed in Table 2 are in some cases meant to refer to combinations of individual programs, as discussed in Appendix B.

¹⁹Except for tax-exempt borrowers, estimates may be found annually in "Special Analysis F," *Special Analyses: Budget of the United States*. Although the estimates are necessarily rough, they serve to provide a general impression of the overall subsidy rate. The calculation of the overall subsidy for tax-exempt borrowers is provided in Appendix B.

TABLE 3—SPECIFICATION OF OTHER PARAMETERS

Sector	L	β	ϕ	r^*	\hat{r}
Mortgage	4.6	-1.80	0.97	0.101	0.103
Farm	2.0	-1.00	0.88	0.078	0.118
Student	0.6	-0.65	0.91	0.032	0.122
Small Business	0.2	-0.80	0.90	0.092	0.127
Tax-Exempt	8.3	-0.40	1.00	0.054	0.099
General Borrowers	81.9	-0.80	1.00	0.100	0.099

Variable	Definition
L	credit allocation as percentage of total credit
β	interest elasticity of loan demand
ϕ	repayment rate
r^*	effective interest rate
\hat{r}	interest rate in the absence of credit subsidies

Notes: Private credit allocations (L) sum to only 97.6, rather than 100, because government for credit subsidies requires 2.4 percent of available credit. The parameters r^* and \hat{r} were calculated on the assumption that $\rho = 0.10$.

Source: See text and Appendix B.

default costs. The composition of the overall subsidy varies considerably across programs.

The parameters used to calculate s^G and s^O are listed next: γ is the guarantee rate, and δ is the proportion of the fee paid by the borrower; both are obtained from government documents. The percentage of default costs not covered by the guarantee fee is given by σ and is calculated in Appendix B.

Table 3 presents estimates of other key parameters. Credit allocations are normalized to equal 100 and are based on recent historical averages. The allocations for each target group are meant to include only federal lending. Consequently, unsubsidized loans (including those for mortgages, farms, etc.) are included in general borrowing. Demand elasticities are obtained from recent studies.

Repayment rates are specified as constants, rather than functions of interest rates (as in Section II), for simplicity and due to the lack of any useful data on the shape of the function. It is still possible to generate rationing outcomes by specifying a maximum effective interest rate for each group and assuming that banks will not lend to the target group at higher rates. The effect of this assumption is to generate a ρ - r curve

that rises linearly to an interior maximum at r_j^* and then falls. Thus, the specification of constant ϕ 's considerably simplifies the calculations without losing any important aspect of the underlying model. For general borrowers, ϕ is set to 1.0. Other reported repayment rates are based on government data and existing studies.

Effective interest rates (r^*) are calculated (as described in Appendix A) on the assumption of $\rho = 0.10$. Estimated interest rates in the absence of credit subsidies are presented in the last column. Credit subsidies lower effective target-group interest rates below those paid by general borrowers for all target groups except mortgage borrowers.

Perhaps the single most important and controversial parameter is the elasticity of supply of funds, or more generally the openness of capital markets. A large literature on this topic has developed from papers by Arnold Harberger (1978, 1980) and Martin Feldstein and Charles Horioka (1980), with mixed conclusions. The supply of credit from domestic sources is also controversial. Robert DeFina (1984) surveys existing results and lists interest elasticities ranging from 0 to 5. This paper employs two alternative assumptions concerning the elasticity of supply: $\alpha = 5.0$ and $\alpha = 0.5$. Using

these extremes will provide bounds for the effects of credit policies and will help indicate which results are robust to alternative views about capital markets.

IV. Results

Before discussing the effects of credit policies, it is necessary to resolve two further issues: 1) the interpretation of existing credit allocations (summarized in Table 3) as representing market-clearing or rationed outcomes and 2) assumptions concerning the allocation of credit without any lending subsidies. I specify two interpretations of existing credit patterns and policies: one in which all groups clear and one in which farmers are rationed but other groups clear.²⁰ The allocation of credit without lending subsidies depends on assumptions about whether the market is rationed with existing credit policies, as well as assumptions concerning the shape of the $p-r$ curve for each group. If all markets clear with existing policies, I examine two scenarios in the world without credit subsidies: (a) all markets clear and (b) tax-exempt and mortgage markets clear, but farmers, students, and small businesses are redlined. These cases are meant to represent optimistic and pessimistic extremes concerning the viability of target-group markets in the absence of credit policy. If the existing credit allocation represents rationing of farmers, I assume that case (b) holds without credit policy.

A. Allocation and Level of Credit

The effects of credit subsidies on the allocation and level of credit are presented in Table 4. Starting from a world with no credit subsidies, as represented by scenario (a) or (b) described above, the introduction of all credit programs generates the base-case allocations listed in Table 3 (reproduced here

for convenience). Many of the aggregate effects depend on the elasticity of supply.

In the high-elasticity case ($\alpha = 5$), credit programs raise private borrowing by between 2.5 percent [scenario (b)] and 4.1 percent [scenario (a)]. Crowding-out effects are very small: general borrowing falls by approximately 1 percent in either scenario. Aggregate target-group investment increases by between 23 percent and 42 percent. With the exception of mortgage borrowers, all target groups experience substantial increases in investment.

If the supply of funds is inelastic ($\alpha = 0.5$), different aggregate patterns emerge. Credit programs have essentially no net effect on aggregate private borrowing. General borrowing falls by between 3.5 percent in scenario (a) and 4.6 percent in scenario (b) but is matched by an equivalent absolute rise in targeted lending.

Table 4 indicates that credit programs exert powerful effects on the allocation of credit to target groups, regardless of the supply elasticity. Other simulations (not reported) indicate that these sectoral effects remain for a wide range of demand elasticities as well.

B. Welfare Effects

Standard welfare analysis (see Harberger, 1971) aggregates consumers' and producers' surplus and assumes that the government has access to lump-sum taxes. The welfare analysis described here is based on the traditional approach, with two qualifications. First, consumers' surplus is multiplied by the probability of repayment, so that borrowers obtain the surplus only if their project succeeds. Second, loan demand is assumed to become flat at $r^* = 50$ percent and to be zero above that point. This affects the level of consumers' surplus but will not affect the difference in welfare effects across policies, unless a group is redlined.

The simulations indicate that credit programs generate sizable efficiency costs. Using 1980–1987 averages for net credit and gross national product (GNP), credit programs are estimated to reduce welfare by 0.27–0.40 percent of GNP. Using 1987 val-

²⁰I assume that farmers are rationed at 80 percent of their desired quantity of loans. It is straightforward to analyze the effects of rationing on other groups as well. The important analytical point, however, is how effects differ across rationing and clearing regimes, which may be illustrated with any single group.

TABLE 4—ALLOCATION OF FUNDS UNDER ALTERNATIVE SCENARIOS

Sector	Base case	$\alpha = 5.0$		$\alpha = 0.5$	
		(a)	(b)	(a)	(b)
Mortgage	4.60	4.48	4.50	4.75	4.87
Farm	2.00	1.31	0	1.36	0
Student	0.60	0.25	0	0.26	0
Small business	0.20	0.15	0	0.16	0
Tax-exempt	8.30	6.50	6.51	6.58	6.62
Total, target groups	15.70	12.69	11.01	13.10	11.49
General borrowers	81.91	82.55	82.76	84.78	85.72
Total, all groups	97.61	95.24	93.77	97.88	97.21
ρ	0.1000	0.0990	0.0987	0.0958	0.0945

Notes: Scenarios are described in the text. For the base case, government borrowing to fund credit programs = 2.39, so total credit sums to 100; for the alternative cases (a) and (b), government borrowing is zero.

TABLE 5—GOVERNMENT COSTS (\$) PER DOLLAR OF INCREMENTAL TARGETED INVESTMENT

Sector	Demand elasticities					
	High		Original		Low	
	(a)	(b)	(a)	(b)	(a)	(b)
Mortgage	0.54	0.66	0.74	0.92	1.29	1.70
Farm	0.53	0.25	0.72	0.25	1.31	0.25
Student	0.43	0.32	0.55	0.32	0.91	0.32
Small business	0.44	0.14	0.62	0.14	1.16	0.14
Tax-exempt	0.62	0.62	0.87	0.88	1.64	1.65
Overall:	0.57	0.43	0.79	0.51	1.44	0.63

Notes: All of the estimates assume that $\alpha = 5.0$. Original demand elasticities are given in Table 3; high (low) elasticities raise (reduce) the original figures by 50 percent.

ues, the welfare loss is 0.25–0.37 percent of GNP, or approximately \$10–15 billion.²¹

The estimates vary somewhat due to assumptions concerning supply and demand elasticities and initial scenarios. Nevertheless, several aspects of the results warrant comment. First is the sheer magnitude: at

1/3 percent of GNP, the welfare loss due to credit programs is substantial. Second, since the results are fairly insensitive to specification of supply or demand elasticities, it is not possible to infer the efficiency costs from the allocational effects. In particular, the absence of crowding out implies only that the costs are borne by agents other than nontargeted investors.

Third, the results indicate the importance of explicitly considering the financing costs of credit programs. For most simulations, the gains and losses to the various borrower groups and suppliers of funds roughly offset each other. *The welfare loss occurs because the programs must be financed.* As shown in Table 5, government costs per dollar of incremental targeted investment are ex-

²¹ These numbers are generated by multiplying the welfare changes when the total credit allocation is 100 by (actual net credit)/100 and dividing by GNP. If demand curves do not become flat until $r^* = 100$ percent, the efficiency cost falls by approximately 5 percent. If resource costs of distortionary taxation are included at 30 cents per dollar of government revenue (see Charles Ballard et al., 1985; Kenneth Judd, 1987), the efficiency cost rises to 0.37–0.55 percent of GNP.

traordinarily high.²² Using $\alpha = 5$ and the original demand elasticities, the costs exceed 50 cents for each group when starting from scenario (a). For scenario (b), the costs are somewhat lower because several groups are redlined initially, but the average cost is still 50 cents. These results are not sensitive to shifts in α . However, increasing demand elasticities by 50 percent raises the average cost to over 90 cents for any group that is not redlined beforehand.

In a perfectly efficient world, the traditional approach would provide all of the necessary information for welfare analysis. However, focusing solely on the aggregate welfare effects may be misleading because, as discussed above, credit programs are often enacted specifically in response to some preexisting distortion, externality, or distributional concern. Although it is beyond the scope of this paper to develop a model explicitly incorporating all of these issues, several useful insights concerning the welfare effects of credit policy can be derived.

First, under all scenarios, all target groups except mortgage borrowers experience large gains in consumer surplus. However, because the programs subsidize both inframarginal and incremental borrowers and because there are no societal benefits to subsidizing the former group, the division of direct welfare benefits should be an important policy concern.

Under scenario (a), the vast majority of direct welfare benefits accrue to target-group members who would have received credit without public assistance. Approximately 76 percent of student welfare gains are inframarginal. For farmers, small businesses, and tax-exempts, 90 percent of the benefits constitute lump-sum transfers. More than 99 percent of mortgage borrowers' welfare gains also fall into this category. Under scenario (b), of course, none of the

gains made by farmers, students, or small businesses are inframarginal.

Therefore, whether credit programs principally aid inframarginal borrowers or new borrowers depends on assumptions concerning the status of sectoral credit markets without lending subsidies. Because credit policy has been an integral part of domestic credit markets for many years, it is difficult to determine with precision which scenario, (a) or (b), is closer to reality.²³ However, whenever the target market clears, any *marginal* increase in subsidies will benefit primarily inframarginal borrowers.

A second issue is the existence of external benefits. Although specification and calculation of external benefits would be extremely complicated, it is possible to calculate how large the benefits would need to be to offset the welfare losses described above. For each program, it is convenient to express the minimum level of external benefits needed to raise welfare as a percentage of the change in the target group's investment. These percentages are called threshold levels and are shown in Table 6.²⁴

Sizable external benefits must occur for current policies to raise welfare. Using the original demand elasticities and $\alpha = 5$, external benefits must be 40–70 percent of the change in target-group investment, if the target-group market clears beforehand. Thresholds for marginal changes in policy are slightly lower than for overall changes. Threshold levels for redlined groups are considerably lower, because the change in target-group investment is much larger. For

²²These figures are calculations of the model, given the definition of government borrowing in equation (6). The numbers bear no relation to any reported budget figure. Federal budgetary treatment of credit programs is highly misleading and inconsistent (see Bosworth et al. [1987], the Congressional Budget Office [1984] or Gale [1990a] for discussion).

²³It is not obvious that students (who have no collateral or credit history) and small businesses (who must be turned down by at least two banks to qualify for a guaranteed loan) would be redlined in the absence of public assistance. For example, parents could borrow on behalf of their children. SBA guarantees are typically for larger loans with longer maturities than private credit to small business. Without guarantees, borrowers could perhaps qualify for shorter-term or smaller loans. In addition, under current SBA regulations, lenders have incentives to reject private applications in hope of acquiring a guarantee.

²⁴Since the estimates assume that investment crowded out by a credit policy contains no external benefits, the threshold levels are lower bounds on the level of external benefits required to raise welfare.

TABLE 6—THRESHOLD LEVELS (PERCENTAGE) FOR ALTERNATIVE CREDIT POLICIES

Sector	Target-group market with no credit subsidy	Proposed policy	Demand elasticity		
			High	Original	Low
Mortgage	clearing	current policy	30	45	90
	clearing	increase in subsidy	31	46	90
Farm	clearing	current policy	52	70	125
	redlined	current policy	13	14	41
Student	clearing	increase in subsidy	55	68	109
	clearing	current policy	41	51	129
	redlined	current policy	26	21	11
	clearing	increase in subsidy	43	47	60
Small business	clearing	current policy	38	57	93
	redlined	current policy	3	~ 0 ^a	-9
Tax-exempts	clearing	increase in subsidy	40	52	89
	clearing	current policy	55	77	143
	clearing	increase in subsidy	50	66	108

Notes: Threshold levels are defined in the text. Estimates use $\alpha = 5.0$. Original demand elasticities are provided in Table 3; high (low) elasticities raise (reduce) the original estimates by 50 percent.

^aBetween 0 and -0.1.

farmers and students, threshold levels fall to 14 percent and 21 percent, respectively. Although these figures may appear to be encouragingly low, they are noteworthy primarily because they are still positive: even if the government creates the market for farm or student loans (with current policies), there is a welfare loss unless sufficient *external* benefits exist. In contrast, SBA guarantees may generate welfare gains even in the absence of external benefits.²⁵

Threshold levels are not sensitive to shifts in α but rise dramatically for lower demand elasticities. Even in the most favorable case of high demand elasticities, threshold levels are on the order of 30–50 percent. Credit programs may generate external benefits of the appropriate magnitude to raise welfare. However, in the absence of any compelling empirical evidence that such benefits occur, the results serve primarily to emphasize the efficiency losses associated with credit interventions.

C. Interactions and the Effects of Credit Rationing

Because credit subsidies reallocate funds and raise the overall rate of return, a program that subsidizes one target group will

²⁵These results do not depend on the assumption that demand becomes flat at $r = 50$ percent.

necessarily affect credit allocations to other groups. The magnitude of the consequent crowding out is clearly an important policy concern. If policies completely or largely offset each other, then the government is spending substantial resources for little net gain.²⁶

Assume that, in the absence of credit programs, target group j receives $D_j(0)$ in funds. When only a subsidy for group j is introduced, the group receives $D_j(j)$. When all current programs exist, group j receives $D_j(\text{all})$. The offset is then measured by:

$$\text{OFFSET}_j = \frac{D_j(j) - D_j(\text{all})}{D_j(j) - D_j(0)}$$

That is, the offset is the percentage of the gain induced by the original credit subsidy that is eliminated by the introduction of all other credit programs. Estimates of offset percentages are shown in Table 7.

Starting from scenario (a) and setting $\alpha = 5$ yields very small interactions for all credit programs except mortgages. Almost two-fifths of the original rise in mortgage credit due to subsidies is eliminated by other

²⁶The importance of such interactions has been recognized independently by Bosworth et al. (1987). They do not quantify these effects, however. Penner and Silbert (1973) focus on interactions among programs that focus on the same target group.

TABLE 7—OFFSETS: THE EFFECTS OF INTERACTIONS AMONG PROGRAMS

Sector	Scenarios with no subsidy	Interpretation of base case	Offsets (percentage)	
			$\alpha = 5.0$	$\alpha = 0.5$
Mortgage	(a)	clearing	38.3	175.0
Farm	(a)	clearing	2.5	10.9
	(b)	rationed ^a	33.8	35.3
	(b)	rationed ^b	17.4	19.8
Student	(a)	clearing	2.6	11.0
Small business	(a)	clearing	3.5	14.9
Tax-exempt	(a)	clearing	1.2	4.9

Notes: Offsets are defined in the text. Estimates shown are based on the demand elasticities reported in Table 3.

^aRationed at 67 percent of notational demand.

^bRationed at 83 percent of notational demand.

programs. This large crowding-out effect occurs because the original subsidy to mortgages is small ($s = 0.02$). Thus, even a small increase in ρ eliminates a substantial percentage of the original benefits. For the other groups, the offset is small because direct subsidies are large.

At the lower value for α , interactions are much larger. For groups other than mortgage borrowers, the interactive effect quadruples: 15 percent of small-business investment gains and 10 percent of increases in farm and student credit are eliminated by other federal credit programs. Although these interactions are unlikely to have important macroeconomic effects, their effects on individual sectors are nonetheless sizable. For mortgage borrowers, the results are even more striking. They would be better off if all subsidies were eliminated. The crowding out induced by other subsidies more than offsets the small direct subsidy provided by government. Thus, as shown in Table 4, mortgage credit falls with the creation of all programs.

Interactions become extremely important when a group (e.g., farmers in Table 7) is rationed given current credit policies. If only a farm policy is introduced from scenario (b), farm credit rises to a point on farmers' notional demand curve. However, as other credit programs are introduced, interest rates rise and make the farmers' rationing constraint bind. Farmers' notional demand at that rate is typically much higher than the residual amount allotted to them. If farmers are rationed at 67 percent (83 percent) of

their notional demand, the offset is approximately 34 percent (18 percent). In any case, if a group is rationed in equilibrium, the offsets will typically be large, regardless of α . Offsets are not sensitive to variations in demand elasticities.

D. Policy Reform

This section uses the model to examine the implications of some recent events and proposals to reform federal credit. Because specific features of individual credit markets may be important in this regard, the results are necessarily exploratory.

Due to the high and rising costs of federal farm credit, many proposals have focused on reducing the subsidy rate. Halving the rate would reduce farm borrowing by 22 percent and would reduce government costs by 60 percent. Elimination would reduce farm credit by 35 percent.

Sharp increases in observed defaults at the FHA have directed a considerable amount of attention to modifying mortgage loan guarantees. If the overall default rate on FHA guarantees ultimately rises to 10 percent (from the 3 percent used above to represent earlier years), the welfare costs of mortgage guarantees would rise fourfold.²⁷ However, mortgage guarantees would still be the *least* subsidized of the five major credit programs analyzed here.

²⁷The results presented in this section are based on $\alpha = 5$, but are not sensitive to changes in α .

Although they occupy only a small portion of modern credit markets, guaranteed loans to students and small businesses have generated a substantial amount of controversy, presumably because of their perceived high costs. However, because of the differing structure of the programs, different methods for reducing costs are warranted. For example, as shown in Table 2, the principal subsidy to students arises from the stipulation that borrowers may defer principal and interest payments until nine months after graduation with no penalty. Elimination of that subsidy reduces the government's costs by 96 percent and reduces loan demand by 60 percent. However, most of the policy debate has focused on collecting defaulted student loans. Eliminating government costs from default (i.e., setting the guarantee fee equal to the loss rate) would reduce government costs by only 23 percent and would reduce demand by 14 percent.

In contrast, most of the benefits of SBA loan guarantees reside in the subsidized guarantee fee. Setting the guarantee fee equal to the loss rate would reduce small business borrowing by 16 percent, but government costs would fall by 70 percent. Thus, defaults are an important issue for SBA loan guarantees, whereas for students, program costs will continue to be large as long as deferral until graduation is allowed.

In its Preferred Lenders' Program, the SBA offers lending institutions significant reductions in paperwork and allows for greater lender discretion in making loans in exchange for reducing the guarantee rate to 75 percent from 90 percent. If the program works as intended, the increased flexibility will attract more lenders to the program, while the reduced guarantee will induce more careful screening. The effect of the program should be to reduce loss rates. If loss rates fall by 2.5 percentage points (from 10 percent to 7.5 percent), the allocation of funds to small business would fall by 1.5 percent, but small business welfare would *rise*, because the probability of repayment increases. Government borrowing for small business would fall by 30 percent and aggre-

gate welfare would *rise* slightly.²⁸ Although this result is speculative, the analysis indicates the potential for credit programs to raise welfare by improving the incentives and organization of sectoral credit markets, while still preserving the basic purpose and nature of the credit policy.

V. Conclusions

The role of government in imperfect capital markets is an issue of obvious theoretical and practical concern. This paper has developed a model of the credit market and simulated the effects of federal credit interventions. Major results are reported in the introduction. Some caveats and possible extensions should be mentioned at this stage. First, because any simulation employs a variety of maintained assumptions and approximations, results should be interpreted as showing the direction and relative magnitude of various effects, rather than as precise estimates.

Second, since the model assumes that all agents are risk-neutral, all assets are perfect substitutes, and rates of return are equalized across assets. However, many assets may not be good substitutes in asset demand (Benjamin Friedman, 1978; Jeffrey Frankel, 1985). In the present context, credit for students, small businesses, and farmers may be poor substitutes for mortgages, tax-exempts, or corporate debt. In that case, if lenders are risk-averse, the crowding-out effect of subsidies aimed at the first set of target groups would be smaller than indicated above, but so would the direct benefits (Penner and Silber, 1973; Friedman, 1978). With a range of substitutabilities among assets, credit policies could actually crowd in investment by other groups (Friedman, 1978). However, given that 75 percent of all net credit advanced is funneled through financial intermediaries (Michael Moran, 1985), which presumably face competitive pressures to maximize profits, the

²⁸Although screening costs would increase, they would at least partially be offset by reduced lender paperwork for the SBA.

assumption of risk neutrality may be a good approximation.²⁹

Sensitivity analysis on a broader scale would consider using an alternative theoretical framework. For example, Stephen Williamson (1987) and de Meza and Webb (1988) rely on monitoring or screening costs to generate imperfect markets. However, simulations of such models may prove difficult, due to the absence of any reliable estimates of those costs. Although de Meza and Webb (1987) show that allowing equity finance can fundamentally change the results derived from the Stiglitz-Weiss framework, borrowers served by federal credit typically do not issue external equity, so eliminating equity contracts does not appear to be a major restriction in this case.

In light of these results, several features of the model presented above make it an excellent candidate for simulations: 1) it allows comparison of market-clearing, rationing, or redlining outcomes; 2) results depend on parameters for which a fair amount of empirical information is available, rather than on screening or monitoring costs; 3) it easily accommodates multiple borrower groups; and 4) welfare effects depend on the particular parameter values, rather than being predetermined by theoretical factors.

Even if alternative models were used, my conjecture is that the basic results would stand: credit policy has important allocational effects, due to the large subsidies provided, and sizable efficiency costs, due to high government-financing costs. These aspects of credit policy appear to drive the results and would have to be incorporated in any theoretical structure.

Perhaps the most important and most difficult extension concerns the connection between credit allocations and real economic activity. The model maintains a simple, direct link: an increase in credit leads to increased real activity. D. C. Rao and Ira Kaminow (1975), Mary Kay Plantés and David Small (1981), and Bosworth et al.

(1987) emphasize that subsidized credit may simply induce borrowers to substitute debt for equity or capital for labor. The borrower may also use the funds for some entirely unrelated purpose. Under this view, changes in credit may not induce any shift in real activity.

Alternatively, if it provided the marginal source of funds for a large project, government may raise private investment by more than the government credit extended. In addition, a subsidy may serve to keep an enterprise viable now and raise investment in the future. Under these scenarios, investment rises by more than the change in government credit.

This paper makes no attempt to resolve these issues. Instead, the one-to-one link between credit and investment may be taken as a benchmark. Future research on federal credit may help to clarify real-financial linkages, perhaps through empirical analyses of individual programs. Another issue is how the design of credit programs influences their effects. It is easy to show that guarantees and subsidies generate differing incentive effects (Gale, 1987). Focusing on incentives can explain some of the divergent default behavior across programs, which were simply taken as given above.

Credit programs may also help explain long-term declines in saving. Student and mortgage guarantees reduce the level of initial wealth required to make sizable purchases of education and housing and thereby reduce one motive to save. Fumio Hayashi et al. (1987) find limited support for this proposition in comparing U.S. and Japanese saving data. Finally, it may be possible to exploit changes in credit programs to test for the nature and importance of liquidity constraints.

APPENDIX A: MODEL CALCULATIONS

Effective Interest Rates

Consider a \$1 loan and assume that all defaults occur in the first period of repayment. Given the probability of repayment, ϕ , the costs of funds, ρ , and the maturity period for loans, m , banks require constant

²⁹However, given the presence of federal deposit insurance, banks may be risk-seeking.

annual loan payments, X_1 , such that

$$(A1) \quad X_1 = \left[\phi \sum_{k=1}^m (1+\rho)^{-k} \right]^{-1}.$$

The implied interest rate, r_1 , is defined by

$$(A2) \quad X_1 = \left[\sum_{k=1}^m (1+r)^{-k} \right]^{-1}.$$

Substitution of (A1) into (A2) yields

$$(A3) \quad \sum_{k=1}^m [(1+\rho)^{-k}] \\ = \phi^{-1} \sum_{k=1}^m [(1+r_1)^{-k}].$$

Equation (A3) describes the determination of effective interest rates, given ρ , ϕ , and m , in the absence of credit subsidies. If the government introduces a loan guarantee, the bank now requires annual payments, X_2 , such that its discounted costs equal its discounted expected receipts, or

$$(A4) \quad \phi X_2 \sum_{k=1}^m [(1+\rho)^{-k}] + (1-\phi)\gamma \\ = 1 + (1-\delta)(1-\sigma)(1-\phi)\gamma.$$

The left side represents expected bank revenues. The last term on the right represents bank payments for the guarantee fee: the fair-insurance cost of the guarantee is $(1-\phi)\gamma$, but the government pays σ , and borrowers pay δ .

The percentage reduction in the present value of loan payments induced by the subsidized loan guarantee, s_G , is found by solving

$$(A5) \quad 1 - s_G \\ = \frac{\delta(1-\sigma)(1-\phi)\gamma + \sum_{k=1}^m X_2/[(1+r_1)^{-k}]}{\sum_{k=1}^m X_1/[(1+r_1)^{-k}]}.$$

This expression gives the ratio of borrower

payments with and without the guarantee. Using (A2) and some algebra, (A5) reduces to

$$(A6) \quad s_G = \sigma(1-\phi)\gamma.$$

Define X_3 as annual borrower payments with guarantees and other subsidies, and define s as the percentage reduction in the present value of loan payments due to all aspects of credit policy. Then,

$$(A7) \quad 1 - s \\ = \frac{\delta(1-\sigma)(1-\phi)\gamma + \sum_{k=1}^m \{X_3/[(1+r_1)^{-k}]\}}{\sum_{k=1}^m \{X_1/[(1+r_1)^{-k}]\}}.$$

Calculations similar to those used in deriving (A6) yield

$$(A8) \quad X_3 = X_1[1 - s - \delta(1-\sigma)(1-\phi)\gamma].$$

Other subsidies ($s^O = s - s_G$) are modeled as further reductions in annual loan payments. Substitution yields

$$(A9) \quad X_2 = X_3 + \frac{s^O}{\phi \sum_{k=1}^m \frac{1}{(1+\rho)^k}}.$$

The effective interest rate for borrowers, r^* , solves

$$(A10) \quad X_3 = \frac{1 - \delta(1-\sigma)(1-\phi)\gamma}{\sum_{k=1}^m [(1+r^*)^{-k}]}.$$

Substitution of (A10) into (A9) and rearranging yields

$$(A11) \quad \frac{1 - [1 - (1-\delta)(1-\sigma)](1-\phi)\gamma - s^O}{\phi[1 - \delta(1-\sigma)(1-\phi)\gamma]} \\ \times \sum_{k=1}^m \frac{1}{(1+r^*)^k} = \sum_{k=1}^m \frac{1}{(1+\rho)^k}.$$

Equation (A11) implicitly defines r^* . In the absence of subsidies, (A11) reduces to (A3).

Government Borrowing

For a guarantee, the government receives $(1-\sigma)(1-\phi)\gamma$ in guarantee fees but expects to pay $(1-\phi)\gamma$ in defaults. Thus, the government cost of a guarantee is s_G as defined by (A6). In addition, when providing the other subsidies described above, the government pays $X_2 - X_3$ with probability ϕ for each period of the loan. The cost to government in each period is $\phi(X_2 - X_3) = \phi s^O X_1 = \phi(s - s_G)X_1$. Total government borrowing requirements, discounted at ρ , are

$$(A12) \quad G_{LG} = s_G + (s - s_G)\phi X_1 \\ \times \sum_{k=1}^m \frac{1}{(1+\rho)^k} = s.$$

Under a direct loan program, receipts are X_3 per period with probability ϕ , and 0 with probability $1-\phi$. From (A8) and (A1), $X_3 = X_2 - s^O X_1$; but since $X_2 = X_1$ for a direct loan, $X_3 = (1-s^O)X_1$. Therefore, expected government borrowing is given by

$$(A13) \quad G_{DL} = 1 - \phi(1-s^O) \sum_{k=1}^m \frac{X_1}{(1+\rho)^k} \\ = s^O = s.$$

In a tax-exempt program, the government forgoes $X_2 - X_3$ in receipts each period with probability ϕ . Government financing costs are given by

$$(A14) \quad G_{TE} = \phi \sum_{k=1}^m \frac{X_2 - X_3}{(1+\rho)^k} \\ = s^O = s.$$

A more detailed version of this Appendix is available upon request.

APPENDIX B: PARAMETER SPECIFICATION

Unless otherwise specified, data are collected from annual versions of "Special Analysis F" of *Special Analyses: Budget of*

the U.S. Government. Primary mortgage guarantees issued by the Federal Housing Administration (FHA) and the Veteran's Administration (VA) cover 100 percent of the outstanding principal and interest ($\gamma = 1$) and are paid for by the borrower ($\delta = 1$). Default rates of 3.0 percent were assumed for both programs, based on evidence from the mid-1980's. FHA fees are 3.8 percent; VA fees are 1.9 percent. Weighting by new credit issued yields the value for σ . The overall reduction in borrower payments is estimated to be 1 percent for FHA and 4.2 percent for VA guarantees. Weighting by new credit issued yields an average reduction of 2 percent.

Student loans are 100-percent guaranteed. Loss rates due to default are approximately 9 percent (Bosworth et al., 1987 pp. 134-5). Therefore, $\phi = 0.91$. Students currently pay the full fee of 5.5 percent, implying $\delta = 1$ and $\sigma = 0.39 (= 1 - 0.055/0.09)$. Other characteristics of the loan program, particularly the deferral of principal and interest at no cost until graduation, substantially reduce borrower costs. Students would have had to pay 41 percent, 47 percent, and 52 percent more (in present-value terms) for loans in 1984, 1985, and 1986, if there were no guarantee program (table F-12 in *Special Analyses: Budget of the U.S. Government*). Therefore, the guarantee reduced borrower payments (in present value) by 29 percent, 32 percent, and 34 percent respectively, in those years. The value of 32 percent is chosen to represent s .

Small Business Administration (SBA) loan guarantees provide timely payment of 90 percent of outstanding principal and interest. The loss rate on SBA guarantees has been estimated at 9.7 percent (Bosworth et al., 1987 p. 93) and 12.5 percent (Michael Boskin and Bradford Barham, 1984 p. 28). Since fees in the mid-1980's were 1 percent of loan volume and are paid by the bank ($\delta = 0$), a loss rate of 11 percent ($\phi = 0.89$) implies that $\sigma = 0.91$. During 1984-1986, SBA guarantees reduced the present value of borrower payments by 10.8 percent, 14.1 percent, and 18.6 percent (based on data in table F-12). Therefore, s is set equal to 0.14.

For tax-exempt borrowing, the only parameter to set is s , the overall reduction in borrower payments. If the non-tax-exempt borrowing rate is 10 percent (the value of ρ below), and tax-exempt rates are 7 percent (a spread consistent with results reported in James Poterba [1986]), tax-exempt status reduces the discounted (at 10 percent) value of borrower payments on a 10-year loan by 19 percent. The rate of default for tax-exempts is set equal to zero.

Direct farm lending is meant to represent an amalgam of government lending programs to the agricultural sector. These include programs in the Farmers' Home Administration (FmHA), Rural Electrical Administration, and Export Credits. During 1984–1986, the loan programs reduced borrower payments by 21.4 percent, 20.0 percent, and 30.0 percent (table F-11). A rough average is $s = 0.25$. Calomiris et al. (1986 table A-2) report delinquency rates of approximately 4.0 percent of loan volume for all agricultural credit during 1982–1985. However, federal credit programs in agriculture undoubtedly have higher default rates; the FmHA is estimated to have held 4.5 percent of its portfolio in delinquent loans in 1980, rising to 23.0 percent in 1985 (General Accounting Office, 1986 p. 53). A loss rate of 0.12 ($\phi = 0.88$) is used in the simulation.

The demand elasticity for general borrowers is assumed to be -0.8 , based on estimates by Robert Hall (1977), Friedman (1978), and Feldstein and Joosung Jun (1987). In the absence of better data, this value is also used for small businesses. The elasticity of mortgage borrowing is set at -1.8 , based on Phoebe Dhyrnes and Paul Taubman (1969). Farm-investment elasticity is set at -1.0 , based on Michael LeBlanc and James Hrubovcak (1986). The elasticity of student loan demand is estimated from figures in Bosworth et al. (1987). The tax-exempt demand elasticity is based on Patric Hendershott and Timothy Koch (1977). Loan maturities were set at 30 years for mortgages, 10 years for students, small businesses, and tax-exempts, and 20 years for farmers, based on data in table F-11 for 1985 and 1986.

Credit allocations are based on flow-of-funds figures from recent years. Since these data are based on net borrowing, while credit subsidies accompany new credit, some adjustments are necessary. Tax-exempt borrowing represented 8.3 percent of net borrowing during 1980–1987 (see Table 1). FHA and VA mortgages accounted for 4.6 percent of net borrowing since 1980. Agricultural lending represented less than 0.1 percent of net borrowing during 1980–1987, because net agricultural lending was negative in several years. Nonetheless, many new agricultural loans were made. During 1970–1985 and 1976–1980, farm credit averaged 4.1 percent and 4.2 percent of net credit, respectively. Since the government has typically provided between one-third and one-half of all agricultural lending (Council of Economic Advisers, 1986 p. 197), federal farm credit is set at 2 percent of aggregate credit. Net guaranteed student loans for 1980–1987 totalled \$29.4 billion, or 0.6 percent of total net borrowing. Net SBA loan guarantees have been negative in recent years, but new SBA disbursements were approximately one-third of guaranteed student lending during 1980–1987, so the SBA allocation is set at 0.2 percent.

Finally, ρ is set at 0.1. Other rates are calculated given equation (A11). Given these parameters, the model may be solved backwards to generate values of a and b_i , the constants in the supply and demand equations. Alternative initial levels of ρ have no appreciable effects on the results, because a and b_i adjust accordingly.

Optimal Public Good Provision with Limited Lump-Sum Taxation

By JOHN DOUGLAS WILSON*

It is often argued that the use of distortionary taxation lowers the optimal provision of public goods below its optimal level in a first-best economy, which contains no restrictions on lump-sum taxation. However, this issue is usually investigated using commodity-tax models that contain no lump-sum taxes. This paper examines a many-consumer economy in which the only tax instruments are commodity taxes and a poll tax (subsidies are negative taxes). The optimal level of public good provision in this economy typically exceeds the first-best level, at least for distributionally neutral public goods. (JEL 321)

Much of the policy debate in recent years about the desirable level of public good provision in the United States seems at least implicitly to involve a comparison between first- and second-best public good levels. First-best policies are of little interest by themselves, since they apply to an economy in which there are no restrictions on the government's ability to employ nondistortionary lump-sum taxes to raise and redistribute income. However, they do serve as a useful benchmark against which the effects of limitations on the availability of lump-sum taxes can be characterized. Second-best policies reflect these limitations. A possible consensus among researchers on this comparison is reflected by the following statement from a well-known undergraduate text: "Since it becomes more costly to obtain public goods when taxation imposes distortions, normally this will imply that the efficient level of public goods is smaller than it would have been with nondistortionary taxation" (Joseph Stiglitz, 1988 p. 140).

It is now well understood by researchers that this claim needs to be carefully qualified. In particular, complementarities between public goods and taxed private goods could make it desirable to raise public spending beyond the first-best level. Fur-

thermore, particular public projects may have desirable consequences for the income distribution in a second-best economy but not in a first-best economy. Yet, if one is thinking about a "general bias," and if one concentrates on efficiency issues by considering only distributionally neutral public goods, then the assertion that the second-best public good level lies below the first-best level would seem to be a safe bet.¹

The basic message of the present paper is that this view must be modified when the availability of administratively simple forms of lump-sum taxation is recognized. It is standard practice to employ single-consumer models to analyze the efficiency issues associated with public good provision. These models allow the economy to be analyzed as though it contains a single consumer, either because all individuals are identical or because the income distribution is optimal. Distortionary commodity taxation is used to raise revenue, but only because the use of lump-sum taxation has been ruled out.² Moving to a many-con-

¹Even without complementarities or distributional problems, the second-best level may exceed the first-best level, but the examples in the literature, including my recent generalization (Wilson, 1990), support the "presumption" that this case normally will not happen.

²An income tax is usually modeled in this static framework as the special case of a commodity-tax system under which labor alone is taxed, or equivalently, all nonlabor commodities are taxed at identical

*Department of Economics, Ballantine Hall, Indiana University, Bloomington, IN 47405. David Starrett and the referees provided valuable comments.

sumer model, in which income-distribution considerations arise, it becomes possible to incorporate administratively feasible forms of lump-sum taxes into the model without destroying the desirability of using commodity taxation. One such lump-sum tax is a uniform poll tax, which is distributed equally across consumers and may be positive or negative.³ Indeed, a negative poll tax (i.e., a poll subsidy) is a component of the much studied and debated negative income tax, and it even surfaced during the 1972 U.S. Presidential Campaign under the name "demogrant."

A poll tax provides the government with a nondistortionary source of marginal finance. Even if the government chooses a negative poll tax, it is free to finance public goods at the margin by making this tax less negative. Thus, the use of a poll tax may eliminate any positive relation between commodity tax rates and public good levels, even though the distortionary commodity taxes are still present to take care of income-distribution problems. For this reason, the standard efficiency argument for setting the second-best public good level below the first-best level may no longer hold. In fact, an important special case of my model yields the opposite conclusion: the second-best level actually lies *above* the first-best level. This result does not rely on the income-distribution effects of public goods, complementarities between public and private goods, or unusual properties of the utility function, all of which are absent. In fact, my assumptions

encompass the case in which a Cobb-Douglas function determines the utility from private commodities, an assumption employed by Anthony Atkinson and Nicholas Stern (1974) and by Mervyn King (1986) to reach the opposite conclusion for a single-consumer model. The basic intuition behind the result is that greater public good provision lowers the total deadweight loss from taxation by transferring resources from the distorted private sector of the economy to the fully controlled public sector. This reduction in deadweight loss represents an additional benefit of public good provision that is absent in the first-best economy.

Moving to the general model introduces additional considerations into the comparison of first- and second-best public good levels. But as a description of a "general bias" for distributionally neutral public goods, the claim that second-best public good levels lie below first-best levels still appears to be unwarranted when the availability of administratively feasible forms of lump-sum taxation is recognized.

The inclusion of poll taxes in a model of optimal public good provision and commodity taxation is certainly not new. Peter Diamond (1975), Atkinson and Stiglitz (1980), Richard Tresch (1981), David Wildasin (1984), King (1986), and David Starrett (1988) all present rules for optimal public good provision in a many-consumer economy with commodity taxes and a poll tax. However, the issue of how distortionary taxation affects public good *levels* is distinct from the issue of how it affects the *rules* for optimal public good provision. Both issues are important, but the distinction between them is sometimes underappreciated. For the "levels issue," a global comparison of first- and second-best public good levels appears to have been limited to simple special cases of single-consumer models, no doubt reflecting recognized difficulties with obtaining general results in this area.

The plan of this paper is as follows. The next two sections formulate the government's maximization problem and derive the crucial optimality conditions. Section III then uses these conditions to derive the main proposition, which suggests that effi-

ad valorem rates. For intertemporal interpretations of the model, the commodity tax rates can be chosen to represent an income tax on both labor and interest income.

³Even a poll tax would entail some administrative costs, but the point here is that such costs would be relatively small. In his masterly survey of optimal tax theory, James Mirrlees (1986, p. 1197) asserts that "There is little difficulty about paying the same subsidy to every individual in the economy; there is not much more difficulty in making the subsidy depend on age. Uniform positive taxes may be a little more difficult. Taxes and subsidies proportional to trade in specified goods or service may also be difficult to administer with perfect accuracy. But, subject to some minor imperfections, we can take it that most such taxes use information that is cheaply and publicly available."

ciency considerations tend to raise the second-best public good level above the first-best level. The first example in Section IV supports this interpretation. In a second example, however, the second-best level lies below the first-best level, because the public good has important distributional effects. Yet the familiar efficiency argument for a relatively low second-best level does not appear in this second example, casting further doubt on its relevance. Section V draws some connections between the results reported here and those in related literature.

1. The Government's Optimization Problem

The economy contains H individuals, who differ in the form of their utility functions. Public goods are treated as a single aggregate quantity that is "pure" in the sense that all individuals receive the same amount, G , which can be provided to additional individuals at no cost (e.g., national defense). The assumption of a pure public good is employed in all of the previously cited references, but it does have important distributional implications, which are later discussed.

For the second-best economy under consideration, all individuals also face the same vector of commodity tax rates and pay the same poll tax, denoted T (possibly negative). Given this tax system and the public good supply, individual h chooses a vector of net demands for private commodities, $\mathbf{x} = (x_1, \dots, x_N)$, to solve the standard consumer problem of maximizing a strictly quasi-concave utility function, subject to a budget constraint:

$$\max_{\mathbf{x}} u^h(\mathbf{x}, G)$$

subject to

$$(1) \quad \sum_i q_i x_i \leq -T$$

where q_i is the consumer price of commodity i , equal to the producer price p_i plus the tax rate t_i . In vector notation, $\mathbf{q} = \mathbf{p} + \mathbf{t}$. The solution to h 's utility-maximization problem defines the demand functions, $x_i^h(\mathbf{q}, G, Y)$,

and the indirect utility function, $v^h(\mathbf{q}, G, Y)$, where Y is lump-sum income, equal to $-T$ in this model. One of the commodities, say 1, may be interpreted as "resources" (usually more specifically described as labor), in which case $x_1^h(\mathbf{q}, G, Y)$ is negative, because individuals are net suppliers of this commodity. Since only relative prices matter, both the consumer and producer price of commodity 1 may be set equal to 1.

This setup follows the common practice of assuming that there are no fixed factors in the economy. By eliminating this obvious nondistortionary source of finance for public expenditures, I place "severe" limits on the availability of lump-sum taxation. It can then be seen whether a very limited form of lump-sum taxation is enough to reverse the conclusions from the single-consumer analysis.

There is no need to assume that all commodities are taxed optimally. Rather, the government can be given control of a vector of "tax instruments," \mathbf{b} , which determines each tax rate according to a function $t_i(\mathbf{b})$. For example, these functions may constrain some commodities to be taxed at identical rates and others not to be taxed at all. They may even fix all tax rates at specific levels, $t_i(\mathbf{b}) = t_i^*$, with changes in the public good supply then being met with changes in the poll tax to balance the government budget. For our purposes, the critical feature of each of these special cases is that the poll tax and public good supplies can be varied independently of the commodity tax rates, at least in a neighborhood of the government's optimum.

The government's problem is to choose \mathbf{b} , T , and G to maximize a generalized utilitarian social welfare function, $\sum_h \Psi(u^h)$ for an increasing and concave function Ψ ,⁴ subject to the economy's production constraint. This constraint is assumed to be linear in private commodities, and public good production is characterized by a convex cost function, de-

⁴This commonly used form of the social welfare function encompasses the utilitarian and Rawlsian objectives as special cases. The assumption of additive separability is not needed for Proposition 1, but it simplifies one of the later examples.

noted $c(G)$. The linearity assumption fixes producer prices, thereby allowing consumer prices to be defined directly as functions of \mathbf{b} : $q_i(\mathbf{b}) = p_i + t_i(\mathbf{b})$.⁵ The government's problem then becomes

$$\max_{\mathbf{b}, T, G} \sum_h \Psi[v^h(\mathbf{q}(\mathbf{b}), G, -T)]$$

subject to

$$(2) \sum_{i,h} p_i x_i^h(\mathbf{q}(\mathbf{b}), G, -T) + c(G) \leq 0.$$

By Walras's law, production constraint (2) implies the government budget constraint.

Omitted from this setup is the requirement that the consumer budget set defined by (1) intersect each individual's "consumption set," which describes his possible net demand vectors (reflecting, for example, the minimum consumption levels required for subsistence). I basically assume that these constraints can be omitted because they are not binding. One simple violation of this assumption is the case in which all commodity tax rates are constrained to equal 0 and some consumers lack sufficiently large endowments of commodities (including time) to pay the poll tax needed to finance the desired level of public good provision. However, for reasonable assumptions about both the availability of commodity taxation and the degree of inequality aversion embodied in the social welfare function, all individuals can be expected to possess endowments that significantly exceed the optimal poll tax in value. The "central case" in Stern's (1976) extensive numerical calculations of optimal linear income-tax schedules includes a poll

subsidy (i.e., a negative poll tax) equal to 34 percent of the average before-tax income (see Stern, 1976 p. 152).

II. First-Order Conditions

To state the first-order conditions for the government's maximization problem, let λ denote the Lagrange multiplier on constraint (2) and use subscripts other than i to denote partial derivatives and a prime to denote a total derivative. The Lagrangian for the government's problem may then be differentiated with respect to G to obtain the first-order condition,

$$(3) \sum_h \beta^h MRS^h - \lambda \left[\sum_{i,h} p_i x_{iG}^h + c'(G) \right] = 0$$

where

$$(4) \beta^h = \Psi'(v^h) \cdot v_Y^h$$

and

$$(5) MRS^h = v_G^h / v_Y^h.$$

The term β^h is individual h 's "social marginal utility of consumption," and MRS^h is h 's marginal rate of substitution between the public good and lump-sum income. By differentiating the Lagrangian with respect to T , one obtains another important first-order condition:

$$(6) \sum_h \left[\beta^h - \lambda \sum_i p_i x_{iT}^h \right] = 0.$$

This section combines these two first-order conditions into an expression that can be used directly to compare first- and second-best public good levels. In accordance with the previous claim that the analysis applies even to the case of an arbitrarily fixed vector of commodity tax rates, no use is made of any first-order conditions for these tax rates.

As a first step, divide both sides of (5) by λ and add and subtract the sum

⁵If the linearity assumption is replaced with the weaker assumption of constant returns to scale and we also assume that all commodities are taxed optimally, then none of the first-order conditions presented here change. The assumption of optimal taxation effectively allows the government to set \mathbf{q} independently of \mathbf{p} , in which case the first-order conditions for optimal taxation and public good provision do not contain changes in producer prices (see Diamond and Mirrlees, 1971). However, the actual comparison of first- and second-best public good levels would now have to deal with differences in producer prices between the two equilibria.

$$\sum_{i,h} p_i x_{iY}^h \text{MRS}^h:$$

$$(7) \quad \sum_h \left[(\beta^h / \lambda) - \sum_i p_i x_{iY}^h \right] \text{MRS}^h - \sum_{i,h} p_i [x_{iG}^h - x_{iY}^h \text{MRS}^h] = c'(G).$$

The term in the second set of square brackets gives the marginal impact of G on h 's net demand for i , compensated by a reduction in income that keeps h on his initial indifference curve. In other words, this term is the derivative with respect to G of h 's compensated demand function, $s_i^h(\mathbf{q}, G, u)$:

$$(8) \quad s_{iG}^h = x_{iG}^h - x_{iY}^h \text{MRS}^h.$$

Thus, the second summation essentially involves only efficiency considerations, which depend only on substitution effects, not income effects.

In contrast, the first summation in (7) measures equity effects. Specifically, the first-order condition for T given by (6) implies that this summation is a covariance between the bracketed term and MRS^h . To interpret this covariance, first define

$$(9) \quad \gamma^h = \beta^h + \lambda \sum_i t_i x_{iY}^h.$$

Diamond (1975) calls γ^h the "social marginal utility of income," because it measures the amount by which social welfare rises when individual h receives another unit of income, taking into account the social value of h 's change in tax payments. Using the equality, $\sum_i (p_i + t_i) x_{iY}^h = 1$, which is implied by the consumer budget constraint, one finds that

$$(10) \quad (\beta^h / \lambda) - \sum_i p_i x_{iY}^h = (\gamma^h / \lambda) - 1.$$

Equations (10) and (6) imply that λ equals the average γ^h and that the first summation in (7) is actually a covariance between γ^h / λ and MRS^h . Then, (7) may be rewritten as a sum of this equity term and the efficiency

term obtained by using (8):

$$(11) \quad - \sum_{i,h} p_i s_{iG}^h(\mathbf{q}^{**}, G^{**}, u^{h**}) + \text{Cov}(\gamma^h / \lambda, \text{MRS}^{h**}) = c'(G^{**})$$

where double asterisks denote the second-best values of variables and the arguments of the compensated demand derivatives in (11) are explicitly included for later reference.

For guidance in the manipulations of (11) needed to compare public good levels, I now introduce a rule for the optimal public good supply in a first-best economy. Such a rule can be obtained directly from (11). With lump-sum taxes available to take care of distributional problems, the covariance drops out. The absence of commodity taxes implies that the first term should be evaluated at $\mathbf{q} = \mathbf{p}$, in which case this term becomes a sum over individuals of the amount by which each individual's expenditures on private commodities must rise to compensate for a unit drop in G . This compensation is the individual's marginal rate of substitution between G and Y :

$$(12) \quad \text{MRS}^h(\mathbf{p}, G, u^h) = - \sum_i p_i s_{iG}^h(\mathbf{p}, G, u^h).$$

Equation (11) therefore becomes the famous "Samuelson condition," requiring that the sum of the marginal rates of substitution equal the marginal cost of public good provision:

$$(13) \quad \sum_h \text{MRS}^h(\mathbf{p}, G^*, u^{h*}) = c'(G^*)$$

where single asterisks denote the first-best values of variables.

The next step in the comparison of public good levels is to decompose (11) into a sum of terms that includes the left side of (13) as one component. This task is accomplished by introducing deadweight-loss considerations explicitly into the analysis. Thus, de-

fine a "loss function" as follows:

$$(14) \quad L(\mathbf{q}, G, \mathbf{u}) = \sum_{i,h} p_i s_i^h(\mathbf{q}, G, u^h) \\ - \sum_{i,h} p_i s_i^h(\mathbf{p}, G, u^h)$$

where $\mathbf{u} = (u^1, \dots, u^H)$ and \mathbf{p} is omitted as an explicit argument of $L(\cdot)$ because it is fixed for the analysis.⁶ In words, this function gives the amount by which the resource cost of the net demands in the equilibrium with taxes $\mathbf{t} = \mathbf{q} - \mathbf{p}$ exceeds the minimum resource cost needed to achieve the given utility vector with the given G . Because taxes distort consumption decisions, this minimum resource cost is achieved only if \mathbf{q} is proportional to \mathbf{p} . Otherwise, the deadweight loss is positive (assuming some substitutability in consumption).

The marginal deadweight loss from an increase in G may now be defined as the partial derivative of the loss function with respect to G . In words, it is the marginal impact of G on the excess resource cost needed to achieve the current utility vector. By substituting this derivative of (14) into (11) and using (12), I obtain

$$(15) \quad \sum_h \text{MRS}^h(\mathbf{p}, G^{**}, u^{h**}) \\ - L_G(\mathbf{q}^{**}, G^{**}, \mathbf{u}^{**}) \\ + \text{Cov}(\gamma^h/\lambda, \text{MRS}^{h**}) = c'(G^{**}).$$

A comparison of (15) with (13) shows that a positive (negative) marginal impact of G on the deadweight loss from taxation contributes negatively (positively) to the marginal benefit of G . Complicating the comparison, however, are "income effects" created by the presence of u^{h**} in (15) and u^{h*} in (13). The impact of these utility differences on the marginal benefit of G may

be described by the difference

$$(16) \quad \sum_h \Delta \text{MRS}^h = \sum_h \text{MRS}^h(\mathbf{p}, G^{**}, u^{h**}) \\ - \sum_h \text{MRS}^h(\mathbf{p}, G^{**}, u^{h*}).$$

Substituting (16) into (15) gives the first-order condition that will be used for the comparison:

$$(17) \quad \sum_h \text{MRS}^h(\mathbf{p}, G^{**}, u^{h*}) \\ - L_G(\mathbf{q}^{**}, G^{**}, \mathbf{u}^{**}) \\ + \text{Cov}(\gamma^h/\lambda, \text{MRS}^{h**}) \\ + \sum_h \Delta \text{MRS}^h = c'(G^{**}).$$

III. The Main Comparison

The main proposition about first- and second-best public good levels will now be presented, proved, and discussed.

PROPOSITION 1: $G^{**} \geq G^*$ as

$$(18) \quad -L_G(\mathbf{q}^{**}, G^{**}, \mathbf{u}^{**}) \\ + \text{Cov}(\gamma^h/\lambda, \text{MRS}^{h**}) \\ + \sum_h \Delta \text{MRS}^h \geq 0.$$

PROOF:

If consumer prices are held fixed at \mathbf{p} (i.e., $\mathbf{t} = \mathbf{0}$), all individuals possess well-defined indifference curves over the public good and lump-sum income. The strict convexity of these indifference curves and the convexity of the cost function $c(G)$ then imply that

$$G^{**} \geq G^* \quad \text{as}$$

$$(19) \quad \left[\sum_h \text{MRS}^h(\mathbf{p}, G^{**}, u^{h*}) - c'(G^{**}) \right] \\ - \left[\sum_h \text{MRS}^h(\mathbf{p}, G^*, u^{h*}) - c'(G^*) \right] \leq 0.$$

⁶This definition is equivalent to J. A. Kay's (1980) definition of the loss function, which generalizes Diamond and Daniel McFadden's (1974) definition.

Subtracting (13) from (17) shows that (19) is equivalent to (18).

Thus, the difference $G^{**} - G^*$ depends positively on three effects: 1) a deadweight-loss effect, given by the negative of the derivative of the loss function with respect to G ; 2) an equity effect, given by the covariance between γ^h/λ and MRS^{h**} ; and 3) an income effect, given by the difference $\sum_h \Delta MRS^h$ in (16). For the purpose of uncovering a "general bias," it seems reasonable to consider the case in which the utility functions exhibit separability between private commodities and the public good, since "...a general project has no obvious net complementarity" (Starrett, 1988 p. 173). In this case, it can be argued intuitively that a marginal rise in G should normally lower the deadweight loss, thereby creating a tendency for G^{**} to exceed G^* . The separability assumption implies that the utility functions take the form, $\bar{u}^h(w^h(x), G)$, where $w^h(x)$ denotes "private utility." With commodity tax rates and total utilities held fixed, a rise in G affects the loss function [defined in (14)] only by reducing private utilities. In other words, a higher G may be viewed as representing a transfer of resources away from the distorted private sector and into the government-controlled public sector. With fewer resources employed in the sector that misallocates them, the deadweight loss should normally be lower.

In general, however, both the second and third effects are also present, and they may both contribute towards making G^{**} fall short of G^* . Assuming G is a strongly normal good, $\sum_h \Delta MRS^h$ is likely to be significantly negative, because the deadweight loss from the distortionary commodity taxes can be expected to lower utilities, at least on average. Under the same normality assumption, however, individuals with high utilities and low social marginal utilities of income are likely to place high marginal values on the public good, in which case the equity effect is also significantly negative. Example 2 in the next section illustrates this reasoning.

Conversely, if one considers a public good that is distributionally neutral, as defined by

a zero equity effect, then one should expect the income effect to be relatively small. In terms of a "general bias" then, Proposition 1 suggests that the government's use of distortionary taxation tends to *raise* the optimal level of distributionally neutral public goods above the first-best level. Example 1 in the next section supports this claim.

Some readers may be puzzled by the complete absence of terms reflecting increased commodity tax rates in Proposition 1, especially since such tax changes are central to the standard argument that the efficiency losses from taxation lower the optimal public good level below its first-best value. A standard envelope-theorem argument explains this absence: if the current G is being optimally financed with the available tax instruments, then the marginal source of finance is irrelevant in the sense that all methods of financing a marginal rise in G have the same welfare impacts. In particular, if poll-tax financing is available and the government is optimizing over available taxes, then it must be the case that the relatively large deadweight loss associated with commodity-tax finance is offset by desirable equity advantages at the margin, making commodity taxes and the poll tax equally attractive at the margin. One may then analyze the desirability of a marginal rise in G by arbitrarily assuming that poll taxes are used to finance it. Hence, the resulting condition contains no changes in commodity tax rates.

IV. Examples

Proposition 1 is now put to work on two interesting examples. In the first example, only the deadweight-loss effect from Proposition 1 is found to be nonzero, and it causes G^{**} to lie above G^* . The second example respecifies the utility function so that the public good is a strongly normal good. As a result, both the income and equity effects become negative, in accordance with the previous contention that the two effects are intimately related to each other. Moreover, these two effects outweigh the deadweight-loss effect, causing G^{**} to fall short of G^* . Taken as a whole, the

examples support the claim that arguments for reducing the second-best public good level below its first-best value must be based on equity considerations, not efficiency considerations.

Example 1: Individuals are endowed only with "resources," and the only innate differences among individuals are endowment differences. With commodity 1 representing resources, the direct utility function for individual h is assumed to take the form, $u[w(r^h + x_1, x_2, \dots, x_N) + f(G)]$, where r^h is his resource endowment, $r^h + x_1$ is then his gross demand for resources ($x_1 < 0$), and the function w is homogeneous of degree one. I will begin the analysis by describing the special forms of the uncompensated and compensated demand functions for this model. The uncompensated demands for consumer h are found by solving h 's utility-maximization problem:

$$(20) \quad \max_x u[w(r^h + x_1, x_2, \dots, x_N) + f(G)]$$

subject to

$$(r^h + x_1) + \sum_{i \geq 2} q_i x_i \leq r^h - T$$

where resources represent the untaxed numeraire (i.e., $q_1 = p_1 = 1$). Since the function w is homogeneous of degree one, the uncompensated demand functions possess the following forms for some function $\theta_i(q)$:

$$(21a) \quad x_i^h(q, G, -T) = (r^h - T)\theta_i(q) \quad i \geq 2$$

$$(21b) \quad x_1^h(q, G, -T) = (r^h - T)\theta_1(q) - r^h.$$

In other words, the net demands do not depend on G and are linear in "full income," defined as $r^h - T$.

To obtain the compensated demand functions, first substitute the uncompensated demand functions back into the direct utility function, giving the indirect utility function:

$$(22) \quad v^h(q, G, -T) = u[(r^h - T)\omega(q) + f(G)]$$

where $\omega(q) = w[\theta_1(q), \dots, \theta_H(q)]$ is the private utility from one unit of full income. Letting $\Omega(G, u)$ represent the private utility needed to achieve total utility u under public good supply G , one may then substitute for $r^h - T$ in (21) to obtain compensated demand functions with the following forms:

$$(23a) \quad s_i^h(q, G, u) = \frac{\Omega(G, u)}{\omega(q)} \theta_i(q) \quad i \geq 2$$

$$(23b) \quad s_1^h(q, G, u) = \frac{\Omega(G, u)}{\omega(q)} \theta_1(q) - r^h.$$

The previous section argued that the loss-function derivative in Proposition 1, $L_G(q, G, \underline{u})$, can be expected to be negative. To check this, substitute (23) into (14) and differentiate:

$$(24) \quad L_G(q, G, \underline{u}) = \sum_h \Omega_G(G, u^h) \times \left\{ \sum_i p_i [\theta_i(q)/\omega(q) - \theta_i(p)/\omega(p)] \right\} = \frac{\sum_h \Omega_G(G, u^h)}{\sum_h \Omega(G, u^h)} L(q, G, \underline{u}).$$

This expression is indeed negative, since commodity taxes create a positive deadweight loss, and private utility $\Omega(G, u^h)$ must fall to compensate for a rise in G .

Thus, G^{**} will exceed G^* , if the income and equity effects described in Proposition 1 do not offset the negative deadweight-loss effect. By (22), the marginal rate of substitution between full income and the public good is $f'(G)/\omega(q)$, which is independent of the value of full income. Since full income is the only dimension along which individuals differ, it follows that the equity effect described by the covariance in (18) equals 0, as does the income effect.

Thus, deadweight-loss considerations prevail, implying that the second-best public good level exceeds the first-best level.

Example 2: To introduce equity effects into the analysis, respecify the first example so that the private utility function continues to be homogeneous of degree one but preferences between private utility and the public good are Cobb-Douglas:

$$(25) \quad u^h(\mathbf{x}, G) \\ = \alpha \log[w(r^h + x_1, x_2, \dots, x_N)] \\ + (1 - \alpha) \log G$$

where $0 < \alpha < 1$. It is worth noting that this specification may be reinterpreted as one in which individuals differ in their abilities to perform labor, if one also assumes a Cobb-Douglas function for private utility. In particular, assume two commodities and write

$$(26) \quad u^h(x_1, x_2, G) \\ = \alpha \log[(r^h + x_1)^\mu (x_2)^{1-\mu}] \\ + (1 - \alpha) \log G$$

where $0 < \mu < 1$. Using the properties of logs, (26) becomes

$$(27) \quad u^h(x_1, x_2, G) \\ = \alpha \log[(1 + x_1/r^h)^\mu (x_2)^{1-\mu}] \\ + \alpha \mu \log r^h + (1 - \alpha) \log G.$$

Since the term $\alpha \mu \log r^h$ is a constant, it can be dropped without altering the analysis in any way, resulting in a model in which x_2 represents consumption and the h th individual works $-x_1/r^h$ hours to earn before-tax income $-x_1$. This specification of individual differences is standard in the optimal-income-tax literature, as originally developed by James Mirrlees (1971). Furthermore, the assumption of Cobb-Douglas preferences for private utilities underlies the single-consumer examples of Atkinson and Stern (1974) and King (1986).

Returning to the more general case of (25), note that (21) and (23) continue to describe the uncompensated and compen-

sated demand functions. Thus, (24) continues to describe the change in deadweight loss. However, this change must now be compared with nonzero income and equity effects. To investigate their signs, note first that the indirect utility function must be modified to account for Cobb-Douglas preferences between private utility and the public good. In particular, substituting (21) into (25) gives

$$(28) \quad v^h(\mathbf{q}, G, -T) \\ = \alpha \log[(r^h - T)\omega(\mathbf{q})] + (1 - \alpha) \log G$$

where $\omega(\mathbf{q})$ again denotes the private utility from one unit of full income. The marginal rate of substitution between the public good and full income is then

$$(29) \quad MRS^h = \frac{1 - \alpha}{\alpha G} (r^h - T).$$

Thus, MRS^h increases with full income. Since the social marginal utility of income declines with full income,⁷ it follows that the covariance term describing the equity effect is negative. A more complex argument, provided in the Appendix, uses (29) to show that the income effect is also negative. In fact, it alone outweighs the deadweight-loss effect, making $G^{**} < G^*$.

Thus, abandoning the assumption of distributional neutrality allows one to construct a reasonable example in which the second-best public good level falls short of the first-best level. Unlike the traditional efficiency argument for contracting the public good supply, this example is based on equity considerations. Moreover, it is important to recognize the limitations of the model which underlie the result, particularly the assumption of a pure public good. If the defining characteristics of public goods

⁷To see this, recall that the social marginal utility of income is $\gamma^h = \beta^h + \lambda \sum_i t_i x_{iy}^h$. The term β^h declines with full income under the Cobb-Douglas assumption, and (21) implies that $\sum_i t_i x_{iy}^h = \sum_i t_i \theta_i(\mathbf{q})$, which is independent of full income. Thus, γ^h declines with full income.

were generalized to allow for limited differences in public good levels across individuals, then such differences could substitute for a system of optimal lump-sum transfers, albeit imperfectly. A more expanded definition of public goods may therefore create an equity argument for greater public good provision in a second-best economy than in a first-best economy. For future research, it would be useful to treat separately different broad categories of public goods when comparing the first- and second-best optima.

V. Related Literature

I have shown that the existence of nondistorting sources of government revenue necessitates a rethinking of how distortionary taxes affect the optimal supply of public goods. David Wildasin (1987a, b) makes a similar point when he criticizes the common belief that the ability of local governments to "export" taxes leads to an overprovision of public goods from the viewpoint of the nation's welfare. This belief runs into trouble when there exist some tax instruments that do not involve exporting (e.g., taxes on nontraded commodities demanded or supplied only by residents). When a local government optimizes over all of its tax instruments, it is indifferent at the margin between "exported" and "own-source" revenues. The possibility of tax exporting then becomes irrelevant for marginal public-expenditure decisions. As a result, Wildasin is able to present an example in which the elimination of tax exporting has no impact on the optimal public good level. The poll tax in the present paper acts in a manner similar to Wildasin's "own-source" revenues by eliminating the negative impact of commodity taxation on the optimal level of public goods.

A real issue in both Wildasin's work and the present paper is whether it is legitimate to assume that governments pursue welfare-maximizing tax policies, given the available tax instruments. If they do not, then there could be a sizable welfare difference between various types of tax finance at the margin. Unfortunately, as Edgar Browning (1976 p. 296) points out, "It is

important to recognize that it is literally impossible to determine the exact source of funds when governments use general-fund financing (enacting tax and expenditure bills separately)." Such a determination is critical for benefit-cost analysis, for which the tax side of government is traditionally taken as exogenous to the problem and the researcher is concerned only with formulating rules for the evaluation of particular public projects. However, the intent of the present paper has not been to treat the tax side as an accurate description of existing U.S. tax policies, but rather to include the tax side as part of the social-welfare optimization problem confronting the government. Such an approach seems appropriate for evaluating the common belief that problems with tax administration depress the desirable level of public good provision by limiting the use of nondistortionary taxes.

Several articles listed at the beginning of this paper discuss how the first- and second-best benefit-cost rules differ in a many-consumer economy. Unfortunately, this literature does not help much with determining how first- and second-best public good levels differ. Atkinson and Stern (1974) thoroughly depict the distinction between the "levels issue" and the "rules issue" in a single-consumer economy with commodity-tax financing. To see the importance of this distinction within the context of the current paper's many-consumer model, rewrite equation (11) as follows:

$$\begin{aligned}
 (30) \quad & \sum_h \text{MRS}^h(\mathbf{q}^{**}, G^{**}, u^{h**}) \\
 & + \sum_{i,h} t_i s_{iG}^h(\mathbf{q}^{**}, G^{**}, u^{h**}) \\
 & + \text{Cov}(\gamma^h/\lambda, \text{MRS}^{h**}) = c'(G^{**})
 \end{aligned}$$

where use is made of the equality

$$\begin{aligned}
 (31) \quad & \text{MRS}^h(\mathbf{q}^{**}, G^{**}, u^{h**}) \\
 & = - \sum_i q_i s_{iG}^h(\mathbf{q}^{**}, G^{**}, u^{h**})
 \end{aligned}$$

(i.e., h 's marginal rate of substitution equals the amount by which his expenditures must rise to maintain his initial utility level following a marginal fall in G). If commodity 1 ("resources") again serves as the numeraire and all taxes are positive, then the second term in (30) is necessarily negative in the first example [see eq. (23a)]. If one ignores the equity term, which is 0 in this same example, then it follows that

$$(32) \quad \sum_h MRS^h(q^{**}, G^{**}, u^{h**}) > c'(G^{**}).$$

In other words, public good expenditures should be carried out to the point at which their marginal benefit, as conventionally measured, still exceeds the marginal cost. King (1986) argues that this result holds in many cases; but it cannot imply that G^{**} lies below G^* , because we have derived the opposite result for the same model.⁸

This apparent conflict in results is resolved by observing that the difference between the optimal public good levels depends on the marginal impact of G on the deadweight loss from taxation, whereas the difference between the two sides of (32) depends on the second term in (30), which has no relation to the deadweight loss measure. As King (1986 p. 283) succinctly describes it, this second term "measures the distortion in the aggregate willingness to pay [for G] resulting from the use of distorting taxes to finance government expenditures." Under the assumptions of the first example, this "distortion" reflects the loss in commodity tax revenue that the government experiences when resources are transferred from the private sector to the public sector via the poll tax. Since individuals do not take this lost revenue into account, they

overvalue the public good from the viewpoint of social welfare.⁹

A final literature that deserves some discussion consists of the many papers that numerically compute the "marginal welfare cost of taxation." Recent examples include Charles Ballard et al. (1985), Browning (1987), and Charles Stuart (1984), all of which have recently been reviewed by Don Fullerton (1989). This literature ignores equity issues, concentrating instead on the marginal deadweight loss (or "marginal excess burden") from various distortionary methods of financing public expenditures at the margin. It generally obtains sizable marginal-loss measures, but Fullerton observes that only Browning's paper, among the three, provides a traditional measure of this marginal loss. He also argues, however, that this measure has limited relevance for benefit-cost analysis, because it does not determine the extent to which the conventional marginal-benefit measure should exceed the conventional marginal-cost measure in second-best economies, a view which is consistent with equation (30) above. Whether it is relevant for the comparison of first- and second-best public good levels depends crucially on the availability of a poll tax.

To understand this last distinction, alter first-order condition (17), on which Proposition 1 is based, to make it applicable to a single-consumer economy. The existence of a single representative consumer eliminates the covariance term, the summation signs, and the superscripts identifying individuals; and the requirement that all government revenue needs be met by distortionary com-

⁸King (1986) later presents a Cobb-Douglas example in which the second-best public good level falls short of the first-best level. However, for this example, he switches to a single-consumer model without poll taxes. As has been seen, it is dangerous to extrapolate the results from single-consumer models to models with many consumers.

⁹Unfortunately, King (1986) also refers to the second term in (30) as the "Pigou term" and claims that it measures the "indirect damage" caused by taxation. A. C. Pigou (1949 pp. 33-4) was concerned with how benefit-cost analysis should account for the distortions created by the taxes needed to finance additional public expenditures. The modern public-economics literature uses loss-function derivatives to measure the cost of these distortions. As explained at the end of Section II, no such derivatives appear in my rules for the optimal public good supply, because a nondistortionary poll tax is available to finance the public good at the margin.

modity taxation is taken into account by supplementing the deadweight-loss term in (17) with an expression measuring the marginal deadweight loss from commodity taxation. With these changes, the optimal G for a single-consumer economy must satisfy

$$(33) \quad \text{MRS}(\mathbf{p}, G^{**}, u^*) - L_G(\mathbf{q}^{**}, G^{**}, u^{**}) \\ - L_q(\mathbf{q}^{**}, G^{**}, u^{**})(dt/dG) \\ + \Delta \text{MRS} = c'(G^{**})$$

where dt/dG denotes the vector of tax changes used to finance G at the margin (as derived from the government's optimal-tax problem).¹⁰ Differentiation of equation (14) shows that the k th element of the vector of partial derivatives, L_q , is $-\sum_i t_i (\partial s_i / \partial q_k)$. Browning confines his analysis to a tax only on labor, which may be represented here by a negative value of $t_1 = q_1 - p_1$, reflecting a subsidy on leisure. In this case, implicit differentiation of the government budget constraint gives the tax change that finances a dollar increase in public good expenditures from the optimum, and one can write the marginal deadweight loss from this tax change as follows:

$$(34) \quad \frac{\partial L(\mathbf{q}^{**}, G^{**}, u^{**})}{\partial q_1} \left(\frac{dt_1}{dG} \right) [c'(G^{**})]^{-1} \\ = \frac{\tau \eta_1}{1 - \tau \eta_1} (1 - \tau \eta_G \varphi)$$

where

$$\tau = -\frac{t_1}{q_1} \quad \eta_1 = \left(\frac{\partial s_1}{\partial q_1} \right) \left(\frac{q_1}{s_1} \right) \\ \eta_G = \left(\frac{\partial s_1}{\partial G} \right) \left(\frac{G}{s_1} \right) \quad \varphi = \frac{-q_1 s_1}{c'(G) \cdot G}$$

with all terms evaluated at their second-best values.¹¹ Browning's numerical calculations

consistently produce sizable values for this type of marginal loss.¹² Because of its presence in the single-consumer economy, it is possible to show that $G^{**} < G^*$ for the types of utility functions considered in Section IV, given the added assumption of a CES (constant elasticity of substitution) private utility function and some mild restrictions on parameter values (see Wilson, 1990).

However, the first example in Section IV gives $G^{**} > G^*$ for the many-consumer case, in which a poll tax is allowed. Moreover, the assumptions in this example do not limit the size of the marginal loss in (34), since they do not restrict the wage elasticity η_1 . Therefore, it appears that any general tendency for the marginal deadweight losses from higher commodity taxes to depress the optimal public good supply vanishes once a reasonable form of lump-sum taxation is introduced into the economy.

APPENDIX

This appendix shows that the income effect in Example 2 is negative and exceeds the deadweight-loss effect in magnitude. To make this comparison, first transform the deadweight-loss effect given by (24) into a more useful expression by implicitly differentiating (28) to solve for the marginal rate of substitution between the public good and private utility:

$$-\Omega_G(G, u^h) = [(1-\alpha)/(\alpha G)] [\Omega(G, u^h)].$$

ancing tax and expenditure change that originates from the optimum has a zero first-order impact on utility. The elasticity η_1 is necessarily positive, since $s_1 < 0$ and $\partial s_1 / \partial q_1 < 0$.

¹²Browning's "preferred estimates" range from 0.318 to 0.469, but both numbers reflect the assumption that the marginal tax rate on labor increases faster than the average tax rate. The only other real difference between (34) and Browning's equation 11 is the presence of the elasticity η_G , which equals 0 under his assumption that the public good and private income are perfect substitutes. Browning also effectively considers the case in which the uncompensated demand derivatives, $\partial x_1 / \partial G$ and $\partial x_1 / \partial q_1$, both equal 0. Here, the government budget constraint gives $dt_1 / dG = c'(G) / x_1$, which reduces the right side of (34) to $\tau \eta_1$, an expression equivalent to Browning's equation 10.

¹⁰Formal proofs of equations (33) and (34) are available from the author upon request.

¹¹Equation (34) can be written in terms of compensated labor-supply elasticities, because any budget-bal-

Substituting this equality into (24) gives

$$(A1) \quad L_G(\mathbf{q}^{**}, G^{**}, \underline{\mathbf{u}}^{**}) \\ = -[(1-\alpha)/(\alpha G)] L(\mathbf{q}^{**}, G^{**}, \underline{\mathbf{u}}^{**})$$

where the double asterisk again denotes the second-best values of variables.

Equation (29) shows that the income effect, as defined by (16), is created by the change in each individual's full income needed to move his utility from its first-best level to its second-best level, given the second-best public good level and no commodity taxes. Letting ΔF^h denote this income change for individual h ,

$$(A2) \quad \sum_h \Delta \text{MRS}^h \\ = [(1-\alpha)/(\alpha G)] \sum_h \Delta F^h.$$

Thus, $\sum_h \Delta F^h$ in (A2) must be compared with $L(\mathbf{q}^{**}, G^{**}, \underline{\mathbf{u}}^{**})$ in (A1).

With consumer prices equaling producer prices in the absence of commodity taxes, the consumer budget constraints require that

$$(A3) \quad \sum_h \Delta F^h = \sum_{i,h} p_i [s_i^h(\mathbf{p}, G^{**}, u^{h**}) \\ - s_i^h(\mathbf{p}, G^{**}, u^{h*})].$$

Then,

$$(A4) \quad \sum_h \Delta F^h = \sum_{i,h} p_i [s_i^h(\mathbf{p}, G^{**}, u^{h**}) \\ - s_i^h(\mathbf{q}^{**}, G^{**}, u^{h**})] \\ + \sum_{i,h} p_i [s_i^h(\mathbf{q}^{**}, G^{**}, u^{h**}) \\ - s_i^h(\mathbf{p}, G^{**}, u^{h*})].$$

Using the definition of the loss function given by (14) in the text, (A4) may be

rewritten as

$$(A5) \quad \sum_h \Delta F^h = -L(\mathbf{q}^{**}, G^{**}, \underline{\mathbf{u}}^{**}) \\ + \sum_{i,h} p_i [s_i^h(\mathbf{q}^{**}, G^{**}, u^{h**}) \\ - s_i^h(\mathbf{p}, G^{**}, u^{h*})].$$

To sign the summation on the right side of (A5), observe first that the second-best optimum must satisfy the economy's production constraint [eq. (2)] with equality:

$$(A6) \quad \sum_{i,h} p_i s_i^h(\mathbf{q}^{**}, G^{**}, u^{h**}) = -c(G^{**}).$$

Furthermore, the nonoptimality of G^{**} in the first-best economy implies that

$$(A7) \quad \sum_{i,h} p_i s_i^h(\mathbf{p}, G^{**}, u^{h*}) \geq -c(G^{**}).$$

(Otherwise, there would exist a feasible way to change G and transfer income across consumers so as to make everyone better off.) Thus, the summation in (A5) is negative, implying that

$$(A8) \quad \sum_h \Delta F^h \leq -L(\mathbf{q}^{**}, G^{**}, \underline{\mathbf{u}}^{**}).$$

Using (A8) to compare (A2) with (A1) gives

$$(A9) \quad \sum_h \Delta \text{MRS}^h < L_G(\mathbf{q}^{**}, G^{**}, \underline{\mathbf{u}}^{**}) < 0$$

(i.e., the income effect is negative and outweighs the deadweight-loss effect). Since the text notes that the equity effect is also negative, Proposition 1 shows that G^{**} must fall short of G^* .

Retrospective Capital Gains Taxation

By ALAN J. AUERBACH*

This paper presents a new approach to the taxation of capital gains that eliminates the deferral advantage of realization-based systems, along with the lock-in effect and tax-arbitrage possibilities associated with this deferral advantage. The new method still taxes capital gains only upon realization but, effectively by charging interest on past gains when realization finally occurs, eliminates the incentive to defer such realization. Unlike a similar scheme suggested previously by Vickrey, the present method does not require knowledge of the potentially unobservable pattern of gains over time. It thus is applicable to a very broad range of capital assets. (JEL 320, 520)

Virtually every country that taxes income imposes a capital gains tax only upon the realization of gains rather than on accrual. Though countries vary with respect to indexing for inflation and the relative tax rates on capital gains and ordinary income, the realization-based tax system sets capital gains taxation apart from other forms of taxation and is associated with a variety of economic distortions.

The most frequently discussed problem arising from taxing capital gains upon realization is the "lock-in" effect, the desire to hold appreciated assets in order to defer taxes on gains already accrued. This effect leads investors to accept a lower before-tax rate of return than they would for new investments without such accrued gains, resulting in a distorted allocation of capital and inefficient portfolio selection.

As an illustration of the lock-in effect, consider a simple two-period example with-

out uncertainty in which an investor, having accrued a first-period gain, g , must decide whether to realize the gain and reinvest at the rate of return, i , or hold the asset for an additional rate of return r . Assuming all capital income is taxed at the same rate, t , then the investor's terminal wealth under the first strategy is

$$\begin{aligned}(1) \quad W_R &= [1 + g(1 - t)][1 + i(1 - t)] \\ &= (1 + g)(1 + i) \\ &\quad - t\{g[1 + i(1 - t)] + (1 + g)i\}.\end{aligned}$$

In second-period units, total taxes equal those paid in the first period, accumulated at the net-of-tax interest rate, plus those due in the second period.

If the investor chooses to hold rather than sell, the terminal wealth is

$$\begin{aligned}(2) \quad W_H &= (1 + g)(1 + r) \\ &\quad - t[(1 + g)(1 + r) - 1] \\ &= (1 + g)(1 + r) - t[g + (1 + g)r]\end{aligned}$$

so that the tax on the first-period gain is deferred, *without interest*, to the second period. This makes the investor willing to hold even for a range of returns $r < i$. The larger is g , the larger the deferral advantage and, hence, the lower r must be to induce the investor to sell.

Research support of the National Science Foundation and the Penn Institute for Law and Economics is gratefully acknowledged. Work on the paper began during a visit to the Financial Markets Group at the London School of Economics. I am grateful to Albert Ando, Doug Bernheim, Jim Hines, Bob McDonald, Jim Poterba, Jeff Strnad, Al Warren, seminar participants at the Universitat Autònoma de Barcelona, Columbia, NBER, Northwestern, Penn, Princeton, and Queens and three anonymous referees for comments on earlier drafts.

Closely related to the lock-in effect is the general problem of tax avoidance facilitated by the voluntary nature of realization. Because losses as well as gains have their tax burdens deferred until realization, investors have the incentive to realize losses immediately, to maximize the associated tax reductions. Aggressive application of the simple rule of holding winners and realizing losers potentially permits individuals to generate tax reductions without incurring major transaction costs (George M. Constantinides, 1983; Joseph E. Stiglitz, 1983).

This arbitrage possibility has led to a second major distortion arising from the present system of capital gains taxation. To prevent investors from generating capital losses to offset ordinary income, tax systems typically limit the allowable annual deduction for such losses. While perhaps representing an effective response to the problem of tax arbitrage, this loss-offset limitation also distorts the choice of investment away from the risky assets which are more likely to produce losses (e.g., Stiglitz, 1969).

Given such problems, there is great appeal to the prospect of switching to a tax on accrued capital gains. Though proposals to adopt accrual taxation have received serious scholarly attention (e.g., David Shakow, 1986), there seems to be little chance that such a system will be adopted on a broad scale.¹ Beyond the criticism that accrual taxation would increase annual taxpayer compliance costs, perhaps the most significant arguments against it are that some assets are hard to value except when they are sold and that liquidity constraints could force the premature sale of indivisible assets simply to pay the accruing taxes.

A potential solution to the problems of both present law and accrual taxation is a realization-based tax that offsets the deferral advantage of holding gains by imposing a higher tax rate on gains held for longer periods of time. The effect is to simulate a

system under which capital gains taxes are computed on an accrual basis but collected, with interest, only upon realization. From a comparison of (1) and (2), it is clear that charging tax-deductible interest on the taxes accruing on unrealized gains would eliminate the deferral advantage. Such an approach was originally conceived by William Vickrey (1939). By construction, it would eliminate the lock-in effect and the tax-arbitrage possibilities generated by selective realization, because of its equivalence to an accrual tax. At the same time, it would also remedy the liquidity problem of accrual taxation by collecting the tax only when sales actually occurred.

Unfortunately, this "cumulative averaging" approach is plagued by the second problem of accrual taxation mentioned above, that of valuation. For assets that are hard for the government to value except when sold, it will be unclear upon sale what the time pattern of accrual of the realized gain was. This will make it impossible to compute retrospectively the tax liability equal in present value to an annual tax on the asset's accrued gains (Jerry R. Green and Eytan Sheshinski, 1978). For example, if an asset has increased in value over a ten-year period, the tax rate on the realized gain needed to simulate accrual taxation would be the ordinary tax rate if the gain occurred entirely in the tenth year, but this tax rate compounded by one plus the relevant interest rate to the ninth power if the entire gain occurred during the first year of ownership. Simply to assume, for tax purposes, that a realized gain accrued smoothly at a constant annual rate would not solve the problem. Assets achieving above-normal rates of return initially would still be subject to a lock-in effect, because an investor anticipating only normal returns from the asset in the future would be able to spread the accrual pattern retrospectively imputed for this gain over several years by holding on to the asset. Likewise, an asset that had declined in value would offer its owner the incentive to sell. Thus, basic arbitrage transactions involving the holding of winners and the sale of losers would still be attractive, though perhaps less so than under a pure realization-based tax.

¹The tax system already has elements that effect accrual taxation, such as the mark-to-market requirements instituted in the 1981 Economic Recovery Tax Act to reduce tax-arbitrage activity involving commodity straddles.

Clearly, many capital assets, such as common shares of large companies, could be marked to market each year to avoid the valuation problem. However, an effective method of dealing with hard-to-value assets would still be necessary to make a switch to accrual taxation or accrual-equivalent realization taxation practical. This paper presents such a method.

The new approach does not require any information on the past pattern of accrued gains and yet eliminates the lock-in effect and the benefits of deferral-based tax arbitrage. In place of the private information on the accrued gains of individual assets, the scheme uses public information, the market interest rate, combined with the assumption of optimal portfolio choice by investors. It does not impose a uniform effective tax rate on accrued gains, *ex post*, but it does impose the same tax rate, *ex ante*, adjusted for risk.

The next section formalizes the criterion that a capital gains tax must satisfy in order not to distort the holding-period decision or allow deferral-based arbitrage. To provide the basic intuition about the new scheme and how it works, Section II presents the results for a special class of assets (such as precious metals) that generate no cash flows or tax liabilities until they are sold. Section III presents the solution for the general class of assets, while Section IV discusses certain limitations of the approach. Section V offers some concluding remarks.

I. Holding-Period Neutrality

The present system of taxation upon realization distorts behavior because the rate at which it taxes the income arising from an asset depends on the size of the asset's previous unrealized gains. This induces both the lock-in effect and deferral-related tax arbitrage.

Suppose that the risk-free interest rate is i ,² and the investor's tax rate on all forms of

income, including realized capital gains, is t . As shown in the example above, an investor holding an appreciated asset will require a before-tax return less than i from that asset to achieve his after-tax opportunity cost of $i(1-t)$, because the tax rate t applied to new gains is offset by the continued deferral, without interest, of taxes payable on the gains already generated but not yet realized.

This distortion would not be present under an accrual tax, which would tax additional income at the same rate regardless of unrealized appreciation or holding period. The result would be a required rate of return independent of these other characteristics. It is this result that we refer to as "holding-period neutrality."

Definition: A realization-based tax system is *holding-period neutral* if it leads each investor in an asset to require a before-tax return having a certainty-equivalent value that is not a function of the length of holding period or the asset's past pattern of returns.

As will be shown below, Vickrey's system of cumulative averaging satisfies this criterion. The challenge is to identify another system with weaker informational requirements that does so as well.

II. Retrospective Taxation

Beginning with a simple case will be helpful. The asset treated in this section is one that generates no cash flows or tax liabilities until it is sold and is taxed only upon sale. Henceforth, the analysis will be in continuous time.

At each date s , the investor (though not necessarily the government) is assumed to know the value of the asset, but not the asset's instantaneous return. Let $V(\cdot)$ be a valuation operator at each date that converts that date's distribution of uncertain returns into their certainty equivalents, from the investor's perspective.³

²If the tax system is not indexed for inflation, then this rate should be viewed as a nominal interest rate. Moreover, in the absence of a risk-free asset, one may reinterpret the paper's results in terms of a "zero-beta" asset that carries no risk premium.

³One can derive the function $V(\cdot)$ from a number of models for the valuation of risky returns, but the model

Consider the class of tax schemes that impose a tax T_s on realization (with $T_0 = 0$). A Vickrey-type tax system would satisfy

$$(3) \quad \dot{T}_s = i(1-t)T_s + tg_s A_s$$

where t is the rate of tax, i is the risk-free interest rate, g_s is the actual, *ex post*, rate of return on the asset at time (after purchase) s , and A_s is the asset's value at date s . As already indicated, though, the tax system described in (3) cannot be imposed retrospectively without knowledge of the time pattern of gains g_s . However, this expression is not a *necessary* condition for a holding-period-neutral tax. The fact that individual decisions are influenced by *ex ante* distributions of returns rather than by *ex post* returns allows us to pursue a weaker condition.

As the scheme in (3) is holding-period neutral (this will be shown formally below) and imposes the rate of tax t on newly accrued capital gains, the investor will require the same before-tax return on the capital asset and the safe asset, adjusting for risk: the certainty-equivalent value of the capital gain g_s will simply equal the investor's before-tax opportunity cost, $V(g_s) = i$. Applying $V(\cdot)$ to both sides of (3) yields

$$(4) \quad V(\dot{T}_s) = i(1-t)T_s + tiA_s.$$

Expression (4) says that the investor faces an increase in the realization-tax liability equal to the interest on the unpaid liability plus the additional tax on the asset based on a rate of return equal to the risk-free rate. Since any scheme satisfying (4) leads the investor to anticipate the same increase in tax liability (adjusting for risk) as would be imposed by the scheme in (3), intuition suggests that the potentially weaker condition (4) will also lead to holding-period neutrality.

itself is not relevant to the paper's remaining discussion. For the interested reader, an appendix to an earlier version of this paper that presents a discussion of the derivation of $V(\cdot)$ is available upon request.

PROPOSITION 1: *Condition (4) is necessary and sufficient for the achievement of holding-period neutrality for the class of assets considered in this section.*

PROOF:

At any date s , the net-of-tax value of an asset to the investor is the value of the asset A_s less the accumulated tax liability T_s . To continue to hold the asset for another instant, the investor requires a certainty-equivalent rate of return equal to the after-tax interest rate $i(1-t)$. Thus, in portfolio equilibrium:⁴

$$(5) \quad V(\dot{A}_s - \dot{T}_s) = (A_s - T_s)i(1-t).$$

Combined with equation (4), (5) implies that $V(\dot{A}_s) = iA_s$, regardless of A_s or s . Hence, (4) implies holding-period neutrality. Combined with the requirement that $V(\dot{A}_s) = iA_s$ for holding-period neutrality, (5) implies (4).

Since the certainty-equivalent value of the before-tax asset return g will equal i when an accrual-equivalent tax is imposed, it is clear that the Vickrey-type tax system described in (3) satisfies (4) and hence is holding-period neutral. As mentioned above, the challenge is to find some other tax scheme also satisfying (4) that has weaker informational requirements. One such tax system exists.

PROPOSITION 2: *Suppose the realization-tax liability at date s is*

$$(6) \quad T_s = (1 - e^{-tis}) A_s.$$

Then, the tax system satisfies (4) for all s and hence is holding-period neutral.

⁴It might be argued that the investor may not achieve an interior solution to the portfolio-choice problem in the case of assets subject to capital gains taxes. For example, one cannot freely buy and sell assets that are indexed by having already been held for a specified time period. However, the focus here is on the case in which the holding period becomes irrelevant to the portfolio-choice problem. A fortiori, the assumption of portfolio balance is justified.

PROOF:

Taking the time derivative of (6), one obtains

$$\begin{aligned}\dot{T}_s &= (1 - e^{-tis})\dot{A}_s + tie^{-tis}A_s \\ &= (1 - e^{-tis})\left(\frac{\dot{A}}{A}\right)_s A_s - (1 - e^{-tis})tiA_s + tiA_s \\ &= (1 - e^{-tis})\left[\left(\frac{\dot{A}}{A}\right)_s - ti\right]A_s + tiA_s.\end{aligned}$$

By Proposition 1, $V(\dot{A}/A) = i$ if (4) is satisfied. The strategy will be to assume $V(\dot{A}/A) = i$. Once it is proved that (4) is satisfied, the assumption will prove correct.⁵

If $V(\dot{A}/A) = i$, then $\dot{A}/A = i + \varepsilon$, where ε is a random return satisfying $V(\varepsilon) = 0$. (Note that, in general, $E(\varepsilon) \neq 0$; it is the risk premium on the risky asset). Hence,

$$\dot{T}_s = (1 - e^{-tis})(i(1 - t) + \varepsilon_s)A_s + tiA_s$$

which, by (6), may be written

$$(7) \quad \dot{T}_s = i(1 - t)T_s + tiA_s + (1 - e^{-tis})\varepsilon_s A_s.$$

Since, by construction, $V(\varepsilon) = 0$, application of $V(\cdot)$ to both sides of (7) yields (4).

A. Interpretation

Clearly, the evolution of the tax liability T_s described by (7) differs from that of the Vickrey-type system based on *ex post* returns described by (3). Since the gain $g = i + \varepsilon$, (7) differs from (3) in taxing the excess return ε at rate $(1 - e^{-tis})$ rather than t . This is a tax rate that starts at 0 and approaches 1 as s approaches ∞ . The tax rate on the excess return has no effect on the investor's welfare, however, because by construction the excess return has zero value to

him (e.g., Roger H. Gordon, 1985; Agnar Sandmo, 1985).⁶

A specific example is useful in demonstrating how this tax system works to eliminate the lock-in effect. Suppose an investor purchases an asset at some date 0 and will dispose of it with certainty at some future date s_2 . At each date s_1 between 0 and s_2 , he has the option of holding the asset or selling it for its date- s_1 value, A_1 , and buying it back. The asset's price at s_2 , A_2 , is uncertain at s_1 but is not influenced by the investor's decision.

Under the realization strategy, the investor pays a tax of $A_1(1 - e^{-its_1})$ at s_1 and $A_2(1 - e^{-it(s_2-s_1)})$ at s_2 . Under the alternative strategy, he pays $A_2(1 - e^{-its_2})$ at s_2 . A comparison of the two cases shows that the choice is between a tax payment of $e^{-its_2}(e^{its_1} - 1)A_1e^{it(s_2-s_1)}$ at s_1 versus $e^{-its_2}(e^{its_1} - 1)A_2$ at s_2 . The certainty-equivalent value of A_2 at s_1 is just $A_1e^{it(s_2-s_1)}$, however, so the investor is indifferent, *ex ante*. The two cases differ only in the *ex post* treatment of the asset's risk premium: by realizing at date s_1 , the investor prepays part of the tax that would be due at date s_2 , with the earlier payment equal in present value to the future tax it replaces.

Proposition 2 offers a very simple system of capital gains taxation. Computation of the tax burden when an asset is sold requires knowledge of the risk-free interest rate, the investor's marginal tax rate, the holding period of the asset, and the final sales price. (Nothing in the proof depends on either i or t being constant, so variations over time in rates of interest and marginal taxation present no difficulty). The initial purchase price, the pattern of accrued gains,

⁶In fact, as Gordon (1985) shows, the same general equilibrium outcome results from tax systems differing only in their treatment of excess returns, if private risk-pooling is efficient. Differences in the riskiness of after-tax returns are offset by differences in the risk characteristics of individual endowments.

⁵It is straightforward to show that this solution for required holding-period yields is unique. That is, there exists no other rate of return $j \neq i$ for which the implied tax rule corresponding to (7) is in fact consistent with the portfolio-balance condition (5) and the assumed rate of return j .

If private risk-pooling is not efficient, taxes on excess returns that have no value to investors may be pooled by the government, creating value and reducing aggregate risk. In this event, the tax rate on risk premia influences the equilibrium outcome, even though the investor's holding-period decision is not distorted.

and the asset's stochastic properties are irrelevant to the calculation. The tax itself is expressed as a time-dependent fraction of the asset's value at sale, with this fraction going from 0 at $s=0$ to 1 as s approaches ∞ .⁷

To interpret the tax formula (6), consider again the Vickrey-type tax system described in (3). For a terminal asset value of A_s , a holding period of s , and a rate of capital gain always equal to the risk-free rate (implying an initial cost of $A_s e^{-is}$), that system would impose a realization-tax liability of

$$(8) \quad T_s = \int_0^s e^{i(1-t)(s-z)} t i (A_s e^{-i(s-z)}) dz \\ = A_s (1 - e^{-its}).$$

Thus, the tax schedule (6) treats investors as if they had arrived at their current position by investing at the risk-free rate. Since in terms of certainty-equivalence this is precisely what they did, the tax system "works" in the same way that a Vickrey-type system would.⁸

Proposition 2 demonstrates that the tax system given in (6) is holding-period neutral. It is natural to ask whether there are other tax systems achieving holding-period neutrality based on the same information. However, Proposition 3 shows that the tax system already discussed is unique.

PROPOSITION 3: *The tax system described in (6) is the only one based on the information set (t, i, s, A_s) that satisfies the condition for holding-period neutrality, (4).*

⁷Since the tax liability is bounded by the asset's value, the liquidity problem is absent under this tax system. Such an accumulating tax liability over time works to remove the lock-in effect only if the tax is eventually imposed. A provision that eliminates capital gains tax liability at death, for example, might cause the lock-in effect to be exacerbated by a move to such a tax system, since investors would have an even greater incentive to hold "to the end."

⁸The admissibility of *ex ante* equivalence in the design of a tax system is discussed in Section IV.

PROOF:

Consider a tax rule based on the admissible information set:

$$(9) \quad T_s = F(t, i, s, A_s).$$

Differentiating (9) with respect to s yields

$$(10) \quad \dot{T}_s = F_s + F_A \dot{A}_s = F_s + F_A A_s (i + \varepsilon_s) \\ = F_s + F_A i A_s + F_A \varepsilon_s.$$

Applying $V(\cdot)$ to (10) and combining the result with (4) and (9) to eliminate $V(\dot{T}_s)$ and T_s , one obtains the partial differential equation

$$(11) \quad \frac{1}{i(1-t)} F_s + \frac{A_s}{1-t} F_A = F + \frac{t A_s}{1-t}.$$

Since the division of assets is arbitrary, it must be the case that F is homogeneous of degree one with respect to A_s . That is, dividing an asset into two pieces and realizing each half separately can have no effect on the capital gains tax liability. Thus, there must exist some function $F^1(\cdot)$ such that

$$(12) \quad F(i, t, s, A_s) = F^1(i, t, s) \cdot A_s.$$

Substituting the expression for F_s and F_A obtained from (12) into (11), one obtains the ordinary differential equation

$$(13) \quad \left(\frac{1}{i(1-t)} \right) \left(\frac{dF^1}{ds} \right) + \frac{1}{1-t} F^1 \\ = F^1 + \frac{t}{1-t}$$

which, combined with the initial condition $F^1(i, t, 0) = 0$, yields the unique solution $F^1(i, t, s) = (1 - e^{-its})$ and hence $T_s = F(i, t, s, A_s) = F^1(i, t, s) \cdot A_s = (1 - e^{-its}) A_s$.

The information set specified in Proposition 3 does not include the asset's initial price, though knowledge of this is required even by the current system of taxation. One's intuition might suggest that adding this piece

of information would offer an alternative rule that would also "work," similar to that given in (6) but based on the initial purchase price plus imputed interest, $A_0 e^{i's}$, rather than the sale price A_s . However, it is easy to show that this scheme would fail to satisfy condition (4). This alternative system would still encourage the holding of assets that to date had appreciated at a rate exceeding the interest rate i , since it would be imputing a normal rate of return on too low a base and, hence, would not fully eliminate the deferral advantage.

B. Extensions

One of the arguments often made for the preservation of a realization-based system of capital gains taxation is that the preferential tax treatment provided by the advantage of deferral has social value. Without judging such desirability directly, one can dispose of this argument on logical grounds by observing that the system described in (6) does not require a uniform effective tax rate on the income from all assets. A tax benefit for capital assets need not be provided via a distortionary deferral advantage.

Let t' be the tax rate on interest-bearing assets and let t be the desired effective tax rate on capital assets, perhaps lower than t' . In this case, the preceding analysis holds if one replaces the before-tax opportunity cost i with $i(1-t')/(1-t)$. That is, replacing (6) with

$$(6') \quad T_s = \left\{ 1 - \exp \left[-ti \left(\frac{1-t'}{1-t} \right) s \right] \right\} A_s$$

taxes income over time according to the rule

$$(7') \quad \dot{T}_s = i(1-t')T_s + ti \left(\frac{1-t'}{1-t} \right) A_s + \left\{ 1 - \exp \left[ti \left(\frac{1-t'}{1-t} \right) s \right] \right\} \varepsilon_s A_s.$$

Once again, the investor is charged the relevant after-tax interest rate $i(1-t')$ on the

outstanding tax liability and is taxed on the certainty-equivalent accruals of income at the capital asset's tax rate t .

Indeed, the system can be applied even if investors vary with respect to $(1-t)/(1-t')$, the ratio of their relative after-tax returns on the safe and risky assets. As long as each investor is in portfolio equilibrium, with his after-tax risk-adjusted return equal to his opportunity cost, application of the tax system in (6') implies that the investor will require a certainty-equivalent before-tax return of $i[(1-t')/(1-t)]$, even if the ratio $(1-t')/(1-t)$ varies across the population. By construction, the risk premium ε equals the total return g minus the required, risk-adjusted before-tax return $i[(1-t')/(1-t)]$, so differences in $(1-t')/(1-t)$ imply different risk premia on the same asset for different investors. However, this is precisely what gives rise to portfolio sorting and clientele formation, with investors holding diversified portfolios but gravitating toward those assets in which they obtain a relatively favorable trade-off between risk and return (Auerbach and Mervyn A. King, 1983). In equilibrium, each investor will require the available risk premium to hold each risky asset, assuming there is an interior solution to the portfolio-choice problem.⁹

III. The General Tax System

Most assets presently subject to capital gains taxes generate cash flows and are subject to tax charges before disposition of the assets themselves. In the case of corporate

⁹Such a solution will not exist, for example, if assets with different tax characteristics have the same return distributions, as in the case of perfect certainty. In such cases, constraints on investors' positions (on borrowing or short sales, perhaps) are required for any equilibrium to exist, and corner solutions for individual portfolios will arise. Here, the equivalence among after-tax returns holds only if shadow prices on the binding constraints are taken into account (see Auerbach and King, 1983). If, for example, an investor held no taxable debt, only tax-exempt municipal bonds, the appropriate after-tax opportunity cost would be the interest rate on municipal bonds.

equities, shareholders receive dividends and pay taxes on them. For other assets, taxes and cash flows may not be so closely tied. For real estate investments qualifying for accelerated depreciation allowances, for example, investors might in some years receive positive cash flows and tax refunds at the same time, and in later years they might pay taxes equal to a substantial fraction of cash flows. This section extends the previous results to the general class of assets with arbitrary patterns of cash flows and tax payments.

Let D_s be the cash distribution received at date s , and let τ_s be the tax payment made at date s . For some assets, one might impose a restriction relating τ_s to D_s , but this is unnecessary for the derivation. To the extent that there are transaction costs associated with purchasing, selling, or holding the asset, these can be treated as negative distributions.

I follow the same strategy as in Section II, first discussing the evolution of the tax liability T that is necessary to ensure holding-period neutrality. As before, I assume initially that the government wishes to tax all asset income at a single rate t .

PROPOSITION 4: *For the general class of assets just described, the following condition is necessary and sufficient for a tax to be holding-period neutral:*

$$(14) \quad V(\dot{T}_s) = i(1-t)T_s + tiA_s - \tau_s.$$

PROOF:

Following the proof of Proposition 1, note that the yield on the net of tax asset value $A - T$ must equal $i(1-t)$. This yield consists of the cash return on the asset D plus the net capital gain $\dot{A} - \dot{T}$ minus the tax payment τ ; thus,¹⁰

$$(15) \quad V(\dot{A}_s - \dot{T}_s) + D_s - \tau_s = (A_s - T_s)i(1-t).$$

Combined with equation (14), (15) implies

that $V(\dot{A}_s) + D_s = iA_s$, regardless of A_s or s . Hence (14) implies holding-period neutrality. Alternatively, combined with the requirement for holding-period neutrality that $V(\dot{A}_s) + D_s = iA_s$ (i.e., that the before-tax return required in the asset be independent of A_s or s), (15) implies (14).

Expression (14) says that, in computing their increase in tax liability \dot{T} , investors should be given credit for taxes paid currently. Again, such a provision is present in Vickrey's original scheme. As before, the rule described in (14) is less restrictive in that it applies to the valuation of returns *ex ante* rather than actual *ex post* returns in each state of nature. Once again, there is a tax system that will satisfy (14) without requiring information on the pattern of an asset's growth in value.

PROPOSITION 5: *Suppose the realization tax liability is*

$$(16) \quad T_s = (1 - e^{-tis})A_s - e^{i(1-t)s} \times \left[\int_0^s (e^{-iz} - e^{-i(1-t)z}) D_z dz + \int_0^s e^{-i(1-t)z} \tau_z dz \right].$$

Then, the tax system satisfies (14) for all s and hence is holding-period neutral.

PROOF:

Taking the time derivative of (16) and substituting the resulting expression back into (16) yields

$$\begin{aligned} \dot{T}_s &= (1 - e^{-tis})\dot{A}_s + tie^{-tis}A_s \\ &\quad + i(1-t)[T_s - (1 - e^{-tis})A_s] \\ &\quad - e^{i(1-t)s}[(e^{-is} - e^{-i(1-t)s})D_s + e^{-i(1-t)s}\tau_s] \\ &= (1 - e^{-tis})\left[\left(\frac{\dot{A}}{A}\right)_s - i\right]A_s + tiA_s \\ &\quad + i(1-t)T_s + (1 - e^{-tis})D_s - \tau_s \\ &= (1 - e^{-tis})\left[\left(\frac{\dot{A}}{A}\right)_s + D_s - i\right]A_s \\ &\quad + tiA_s + i(1-t)T_s - \tau_s. \end{aligned}$$

¹⁰The derivation assumes for simplicity that D_s and τ_s are known at date s , but this does not affect the results.

Again, without restriction (see the proof of Proposition 2) one may assume that the risk-adjusted, before-tax required return $V(\dot{A}/A) + D = i$, so that $(\dot{A}/A) + D = i + \epsilon$ with $V(\epsilon) = 0$. Thus,

$$(17) \quad \dot{T}_s = i(1-t)T_s + tiA_s - \tau_s \\ + (1 - e^{-tis})\epsilon_s A_s.$$

Since, by construction, $V(\epsilon) = 0$, application of $V(\cdot)$ to both sides of (17) yields (14).

As in the previous case, the solution involves taxing the asset's risk premium at a rate $(1 - e^{-tis})$ rather than t . A way of interpreting (16) is to rewrite it as

$$(16') \quad T_s = (1 - e^{-tis}) \left(A_s + \int_0^s e^{i(s-z)} D_z dz \right) \\ - \left(\int_0^s e^{i(s-z)} D_z dz - \int_0^s e^{i(1-t)(s-z)} D_z dz \right) \\ - \int_0^s e^{i(1-t)(s-z)} \tau_z dz.$$

The term $(A_s + \int_0^s e^{i(s-z)} D_z dz)$ is the present value, at date s , of the asset plus all previous distributions. Thus, the tax scheme begins by treating this entire value as subject to the tax rate $(1 - e^{-tis})$, as in Section II. Had all distributions been received tax-free and reinvested in the asset itself, this would be appropriate, for then the asset would be of the type analyzed there. However, because taxes have been paid in the past and the distributions invested elsewhere, two corrections are necessary for taxes already paid. The last term in (16') is a credit for taxes already paid directly on the asset, while the middle term in (16') is an imputation for taxes paid on the income generated by distributions invested in other assets facing an income tax rate t . That is, the treatment of distributions as having been reinvested in the same asset assumes that they continue to generate income at the before-tax rate of return i , adjusted for risk. Since they were actually invested in other assets, which we may assume to face an accrual-equivalent income tax rate t , we are therefore ignoring the subsequent in-

come taxes attributable to such reinvested distributions. The present value of these imputed taxes at date s is $(\int_0^s e^{i(s-z)} D_z dz - \int_0^s e^{i(1-t)(s-z)} D_z dz)$. Thus, the tax system in (16) can be interpreted as treating all distributions as being reinvested and then applying the tax scheme described in Section II but giving credit for taxes paid along the way.

Yet another interpretation of expression (16) is obtained from the following logic. As is well known, share repurchases and dividends are equivalent except for their tax treatment, and in this case, even the tax treatment is the same. Thus, one should be able to view each distribution as a share repurchase. Since each such repurchase amounts to the investor's realization of part of his assets, consistent treatment based on Proposition 1 ought to suffice. If each "partial" asset sale receives such treatment, there ought to be no deviation needed when the remainder of the asset is sold. Indeed, this conjecture is correct. Collecting terms in (16), one obtains

$$(16'') \quad T_s = (1 - e^{-tis}) A_s \\ + \int_0^s e^{i(1-t)(s-z)} [(1 - e^{-tiz}) D_z - \tau_z] dz$$

which says that the household's tax liability at date s equals the normal tax due on assets without previous distributions or tax payments plus the accumulated deficit in tax payments on previous "realizations" (i.e., distributions).¹¹

Thus, one very simple approach to the achievement of holding-period neutrality is to tax every distribution from a capital asset at the rate $(1 - e^{-tis})$, where s is the time since the asset's purchase. In this event, the informational requirements are no worse than in the previous case without distributions.

More generally, expression (16) is more complex than expression (6), but its infor-

¹¹It is particularly clear from (16'') why the initial purchase price does not appear in the tax calculation. One could view this initial cost as a negative distribution at date zero, but the appropriate tax on this negative distribution would be zero.

mational requirements are still minimal. In addition to what was needed in the previous case, the government now must also know the flows of previous taxes and distributions on the asset.

A record of previous taxes can be obtained from past tax returns. In many instances, as with common stock, the taxes are directly based on the distributions, so records of the distributions themselves are just as easily available. Even in cases for which the taxes τ and distributions D are not so simply related (real estate investments, for example), the law requires taxpayers to supply enough information so that the distributions can be calculated. For example, a real estate investor would add interest payments and depreciation deductions back to reported profits in order to calculate the distribution from a property in a given year.

As before, the tax rule can be extended to the case of different tax rates on capital assets (t) and other income (t') by replacing the interest rate i with the required before-tax return $i(1-t')/(1-t)$. For cases in which t is known, this is a simple change. There are more complicated cases, though, in which tax preferences are given not via a reduction in t but through tax credits or accelerated depreciation, each of which affects the present value of τ . In this case, it is necessary to determine what effective tax rate t is desired and to base the calculation in (16) on this value. Once this has been done, the continued presence or absence of tax credits or accelerated depreciation becomes irrelevant, for variations in these are simply offset by changes in the last term of (16).

IV. Qualifications

The system derived in the preceding sections for taxing capital gains on realization has obvious benefits, but there are potential limitations as well, some of which are discussed in this section.

A. *Ex Ante* versus *Ex Post* Taxation

One potential objection to the tax system developed in this paper is that its equivalence

to accrual taxation is on an *ex ante* basis; at each date s investors are indifferent between the increase in tax liability \dot{T}_s and accrual taxation of additional income, before they know what their income will be. However, on an *ex post* basis, the tax liabilities are not the same. In particular, it is possible for an investor to lose money continuously (A_s declining monotonically with s) and still be liable for taxes on an asset sale.

There are several responses to this criticism. First, even a system of accrual taxation, if deferred with interest as proposed by Vickrey, could lead to a positive tax liability on a capital loss.¹² Second, there are many other examples in which *ex ante* equivalence has been relied upon in the tax literature: for example, in the discussion of the conditional equivalence of consumption and wage taxes (see U.S. Treasury, 1977). Finally, the perception that this tax is unfair to those with below-normal rates of return is quite dependent on the frame of reference of a tax on *ex post* income. If, for example, one used a tax on *ex post* wealth as the frame of reference, the opposite result would hold: the tax scheme would discriminate *against* those with relatively favorable experience.

To see this, note first that a tax at rate t on an imputed rate of return i on an asset is equivalent to a wealth tax at rate ti . Thus, one may reinterpret the scheme in (6) and (16) as simulating an annual wealth tax on an asset whose value is unknown to the government. Given this interpretation, the asset whose value has risen slowly over time will have past values of wealth used for imputation [see (8)] that are too low; they will be assumed to have grown more rapidly in value over time than they actually have. The opposite will be true of assets that have appreciated rapidly.

The issue of fairness, then, involves wealth taxation to an even greater extent than

¹²For example, suppose an asset is purchased for 1 dollar, increases in value to 2 dollars and then decreases to 99 cents. The initial capital gain of 1, with interest, will exceed in absolute value the subsequent capital loss of 1.01 as long as the after-tax interest rate is greater than 1 percent.

ex ante income taxation. If the scheme considered in this paper is "unfair," then so surely must be a system of *ex post* wealth taxation. Since such property taxation is a main source of revenue for state and local governments in the United States, one must question the conclusion or at least recognize that other factors, such as ease of administrability, may outweigh the concern for *ex post* fairness in the design of policy.

B. Closely Held Assets

The system evaluated here would work best for those assets held "at arm's length," in legal terminology. This obviously includes most common stock in public corporations and other similar assets. While most common stock would be relatively easy to value and, hence, could be administered even under a system of accrual taxation, many assets in whose management the typical investor does not play an active role are nevertheless not traded at readily observable (to the government) prices. Examples would include limited partnerships and other assets which the Tax Reform Act of 1986 classifies as "passive" investments.

An asset not in this category, for example an entrepreneur-owned enterprise, would be subject to two problems. First, it would be difficult to distinguish payments to capital [taxes on which, according to (16), would be credited against ultimate capital gains tax liability] from payments to labor (which could not be so credited). Second, part of the initial value of such enterprises represents the capitalized idea of the entrepreneur. The system of retrospective taxation would tax the *income* on such initial capital appropriately but would not tax the initial income associated with the capitalization of the successful idea.¹³ This can be

compared to the current system, which taxes the initial income only upon realization and, hence, at a low effective rate, thereby introducing a powerful lock-in effect (or an incentive to be taken over by another company in order to obtain a tax-free conversion into a more diversified company's shares). In general, this is a relatively small class of assets which pose problems of administration even for the present tax system.

Just as entrepreneurs may avoid tax on labor income contributed to their enterprises under the new system, so may investors who devote labor effort to the choice of investments, in a sense producing a portfolio as the joint product of labor input and invested funds. However, this is a relatively insignificant issue for assets held at arm's length. A major exception to this conclusion would seem to arise in the case of professional securities traders, who devote most of their labor input to this endeavor. However, such income is taxed as ordinary income without any deferral advantage, even under present law. Such treatment would presumably continue even if retrospective taxation were introduced for other investors.¹⁴

V. Conclusions

This paper has presented a scheme that taxes capital gains upon realization without inducing a lock-in effect or providing the opportunity for tax arbitrage. The scheme requires information that is either publicly available (such as interest rates) or present on previous tax returns (such as past tax payments) but not the private (or potentially

case, in which the entrepreneur adds the product of his human capital and then sells the augmented asset immediately (i.e., at $s = 0$), formal adherence to the rule would produce a tax liability of zero. However, one would presumably wish to apply special rules in such special and easily identifiable cases.

¹³To see this, note that the embodiment of the idea in the asset increases the asset's value by the present value of the risk-adjusted returns that the idea is projected to yield in the future. When the investor ultimately sells the asset, the returns on the part due initially to the investor's idea are effectively taxed at the same rate as the returns on the part of the asset purchased using after-tax funds: there is no distinction regarding the source of funds, only a distinction regarding when the asset was obtained. In the simplest

¹⁴If owner-occupied housing were subject to capital gains taxation, then a significant way of achieving untaxed labor income under the new scheme (rather than having labor income eventually included in the capital gains tax base) would be to work on one's house. However, capital gains on houses are, even now, largely excluded from the tax base because of the provisions allowing the rollover of gains and the one-time exemption for individuals over age 55. Thus, even current law permits most such labor income to escape tax entirely.

even unavailable) information on the time pattern of an asset's accrued gains.

Nothing about the tax system described here requires that all asset income be taxed at the same rate for a particular investor. Purchases of certain assets can still be encouraged through a lower overall tax burden, without the need to resort to ad hoc measures such as accelerated depreciation or distortionary measures such as low rates of realization-based capital gains taxes that exacerbate the lock-in effect and the problem of tax arbitrage.

In achieving the economic benefits of accrual taxation without its associated liquidity or information problems, the new approach makes a less distortionary capital gains tax more feasible and eliminates the need for the additional distortions associated with compensating antiarbitrage provisions such as limited loss offsets.

Moral Hazard and Nonmarket Institutions: Dysfunctional Crowding Out or Peer Monitoring?

By RICHARD ARNOTT AND JOSEPH E. STIGLITZ*

We examine a situation in which insurance is characterized by moral hazard. When market insurance is provided, supplementary mutual assistance between family and friends (unobservable to market insurers) will occur. When nonmarket insurers have no better information than market insurers, the mutual assistance not only crowds out market insurance but is also harmful and therefore dysfunctional. Alternatively, when nonmarket insurers can observe each other's effort perfectly, mutual assistance is beneficial. These results point to the potential importance of peer-monitoring mechanisms in mitigating moral hazard. (JEL 026)

The economics literature over the past 15 years has directed attention to the ubiquity of moral-hazard and incentives problems. One way the market responds to moral hazard is to provide only partial insurance, since then individuals still have *some* incentive to take care to avoid the accident. However, they must then bear more risk than they would like. A principal function of many nonmarket institutions, meanwhile, is to help those who have suffered some misfortune, which entails the provision of insurance: the marriage vows formalize and sanctify the mutual insurance aspects of the family; the acid test of a friend is his willingness to help in times of need; charity is regarded as meritorious and is subsidized by the government; and many government social assistance programs, such as unemployment insurance and workmen's compensation, have a strong insurance component. The importance of nonmarket insurance is illustrated by what happens if an individual

catches pneumonia as a result of going on a hiking trip with inadequate rain gear. His employer gives him compensated sick leave; part or all of his medical expenses are reimbursed by his insurance policy or the state; uncovered medical expenses may be partially deductible from his income tax; and family and friends rally round to provide other forms of support. Such extensive support, while directly helpful, deleteriously affects individuals' care to avoid accidents. In terms of the example, had the individual borne all the costs of catching pneumonia himself, he might have taken the trouble to carry adequate rain gear. Thus, it is not obvious that the insurance provided by nonmarket institutions is always beneficial or, more specifically, whether nonmarket insurance institutions, when they supplement market insurance, improve the economy's ability to handle the moral-hazard trade-off between risk-bearing and incentives.

We address this issue by inquiring whether the reciprocal provision of insurance within families and between friends, which we term nonmarket insurance,¹ is welfare-improving when it supplements market insurance. We

We thank the referees and the seminar participants at Stanford University, in particular Ken Judd and Suzanne Scotchmer, for very helpful comments.

¹The term "social insurance" is perhaps more appropriate but is used in some countries to refer to social security. The term "informal insurance" is appropriate for the example, but the phenomenon we identify arises in formal, nonmarket institutions as well.

assume that a market insurer can observe his clients' market insurance purchases but not the nonmarket insurance they obtain through informal arrangements. We first show that nonmarket insurance will always be provided. Moral hazard causes fully insured individuals to expend too little effort. In response, the competitively determined market insurance contract rations the amount of insurance that can be obtained at the equilibrium price. The contract achieves this by specifying both a price and a quantity and by stipulating that it will pay in the event of accident only if the insured has no additional market insurance. Insured individuals would like to obtain additional insurance at the market price. Since they take the market insurance contract as given, they perceive that they can effectively do so by entering into informal insurance arrangements. They neglect that when everyone enters into such arrangements, the accident frequency will change, as will the market insurance contract.

After showing that nonmarket insurance will always be provided, we ask whether the level of expected utility is higher with such insurance than without it. The moral-hazard problem arises because of the inability of the insurance firm to monitor the actions of the insured. There are often other individuals, such as the members of the insured's family, who are in a better position to monitor the insured's action than the insurance firm. The welfare consequences of nonmarket insurance turn out to depend on whether these monitoring capabilities can be effectively harnessed to reduce the moral-hazard problem. If the members of the family (the providers of nonmarket insurance) do not monitor each other, we show that such nonmarket insurance always lowers welfare. The nonmarket insurance leads individuals to take less care; market insurance firms respond by providing less insurance; thus, in the new equilibrium, nonmarket insurance displaces market insurance. Since nonmarket insurance involves less risk-pooling, welfare is reduced; the less-effective insurance crowds out the more-effective insurance. The nonmarket insurance is dysfunctional.

If, alternatively, the members of the family do monitor each other, they will take

greater care than they would without monitoring, which mitigates the moral-hazard problem. Thus, there appear to be two offsetting effects, the risk-pooling advantages of market insurance versus the monitoring advantages of nonmarket insurance. However, it turns out that, with perfect monitoring within the family, the latter effect dominates, and the nonmarket insurance is welfare-enhancing.

This is an example of what we call *peer monitoring*. Peer monitoring is an important mechanism for controlling moral hazard. It arises in credit markets. In less-developed countries, loans are often made to groups of individuals; the members of a group then have an incentive to monitor each other. In developed countries, one of the functions of co-signers on loans is to provide additional monitoring. Partnership arrangements also encourage monitoring. Peer monitoring is also important in labor markets; workers are often in a better position to monitor their co-workers than are employers, which may be one of the advantages of team production.

This raises an intriguing issue related to mechanism design with a principal and many agents when moral hazard is present. The principal can monitor his agents himself (direct monitoring), hire a supervisor to monitor his agents (supervision), or set up a mechanism to induce agents to monitor each other (indirect monitoring). While the literature has considered direct monitoring (e.g., Steven Shavell, 1979; Bengt Holmstrom, 1979) and supervision (e.g., James Mirrlees, 1976; Stiglitz, 1975; Jean Tirole, 1988), it has largely ignored the design of indirect monitoring systems.² An indirect monitoring system will encourage peer monitoring through the creation of interdependence: the dependence of one agent's utility on others' effort. A good example is a university department. A faculty member's utility depends not only on his salary, perfor-

²One exception is H. Lorne Carmichael (1988). He considers peer review in the university setting, which is a form of indirect monitoring system, and argues that the institution of tenure is needed to make peer review incentive-compatible.

mance, reputation, and working conditions, but also directly on his department's and university's reputation. Furthermore, his salary, performance, reputation, and working conditions all depend to some extent on the department's quality. For these reasons, faculty members have a strong incentive to monitor one another's performance, which they do through peer review, teaching evaluations, and so on. In other contexts, production may be physically organized to facilitate peer monitoring; the open office, the assembly line, and team production are examples. In this paper, we treat the peer-monitoring system as exogenous and examine only the extreme cases in which there is either perfect monitoring or no monitoring.

I. The Basic Model without Nonmarket Insurance

Moral hazard is an asymmetric-information phenomenon, and its defining characteristic is hidden action. In the context of insurance, the probability distribution of observable outcomes depends on the insured's unobservable actions. The insurer would like to write insurance contingent on the insured's actions but, since these are unobservable, must base his insurance on observable outcomes. Because of moral hazard, there is a trade-off between risk-bearing and incentives in the provision of insurance. At one extreme, if full insurance is provided,³ the insured is equally well off whatever the outcome and therefore has no incentive to take care. At the other extreme, if no insurance is provided, the individual faces the appropriate incentives but is fully exposed to risk.

We first describe the canonical moral-hazard model without nonmarket insurance (Arnott and Stiglitz, 1988a). There is a single, fixed-damage accident. The probability of its occurrence, p , depends on the individual's effort at accident avoidance, e . The probability-of-accident function is strictly convex: $p' < 0$, $p'' > 0$. The individual's

wealth is w , and d is the damage caused by the accident.

If an accident occurs, the individual receives a (net of premium) payout of α , and his consumption is

$$(1a) \quad y_1 = w - d + \alpha.$$

If an accident does not occur, he pays the premium β , and his consumption is

$$(1b) \quad y_0 = w - \beta.$$

For simplicity, we assume a separable, event-independent utility function.⁴ Expected utility is then

$$(2) \quad EU = u(y_0)(1 - p) + u(y_1)p - e$$

with $u' > 0$, $u'' < 0$.

The individual chooses effort so as to maximize expected utility, taking α and β as given:⁵

$$(3) \quad e(\alpha, \beta) = \underset{(e)}{\operatorname{argmax}} EU(\alpha, \beta, e).$$

It is straightforward to show that, with the form of utility function assumed, $\partial e / \partial \alpha < 0$ and $\partial e / \partial \beta < 0$; as more insurance is provided, the individual reduces effort. Substitution of (3) into (2) gives $V(\alpha, \beta) \equiv EU(\alpha, \beta, e(\alpha, \beta))$, from which an individual's indifference curves in $\alpha - \beta$ space can be plotted (see Fig. 1). The slope of an indifference curve is

$$(4) \quad \left. \frac{d\beta}{d\alpha} \right|_{\bar{V}} = \frac{u'_1 p}{u'_0(1 - p)}$$

where $u_0 \equiv u(y_0)$ and $u_1 \equiv u(y_1)$. The locus of (α, β) for which there are zero profits, the zero-profit locus (ZPL), is $(1 - p)\beta - p\alpha = 0$. Substitution of (3) into this equation

⁴The general form of the utility function with event i is $U_i(y_i, e)$. Separability implies $U_i(y_i, e) = u_i(y_i) - e$. Event-independence implies that the utility-from-consumption function $u_i(y)$ is independent of the event; the accident causes neither pain nor pleasure and does not alter tastes.

⁵Throughout the paper, we ignore the complications that arise from the possibility that $e = 0$.

³Full insurance—equalization of the marginal utilities of income in all events—implies no incentive to take care when the utility function is event-independent, which we assume, but not generally otherwise.

FIGURE 1. THE INDIVIDUAL PERCEIVES THAT HE CAN OBTAIN ADDITIONAL INSURANCE AT THE MARKET PRICE BY ENTERING INTO A MUTUAL INSURANCE PACT

gives the ZPL as a function of α and β , which is plotted in Figure 1. Its slope is

$$(5) \quad \left. \frac{d\beta}{d\alpha} \right|_{ZPL} = \frac{p + (\alpha + \beta)p'(\partial e / \partial \alpha)}{(1-p) - (\alpha + \beta)p'(\partial e / \partial \beta)}$$

In Figure 1, Ω is the point of optimal insurance, contingent on the unobservability of effort;⁶ it occurs at the point of maximum utility on the zero-profit locus.

We now investigate competitive equilibrium for this model with insurance purchases observable (Arnott and Stiglitz, 1988a, b). Define $q \equiv \beta/\alpha$ to be the price of insurance. Since Ω is on the ZPL, $q_\Omega \equiv (\beta/\alpha)_\Omega = [p/(1-p)]_\Omega$. The precise shapes of the indifference curves and the ZPL are inessential for our analysis.⁷ What is essen-

⁶ Ω is the optimal *deterministic* contract. The circumstances in which randomization is Pareto-improving are investigated in Arnott and Stiglitz (1988c).

⁷Indifference curves are positively sloped and can be nonconvex

$$\left(\left. \frac{d^2\beta}{d\alpha^2} \right|_v > 0 \right)$$

as can be seen from (4). As the amount of insurance provided increases, holding utility fixed, u'_1/u'_0 falls,

tial, however, is that at Ω the slope of the ZPL exceeds the price of insurance. Since indifference curves are positively sloped and since Ω is at a point of tangency of an indifference curve and the ZPL, the ZPL must be positively sloped at Ω . Now consider increasing α by one unit. To maintain zero profits, β must be increased by more than the price of insurance, $q_\Omega = [p/(1-p)]_\Omega$. An increase in β of $[p/(1-p)]_\Omega$ causes zero profit to be made on the *marginal* unit of insurance; but the increase in α raises the probability of accident, and so β has to be increased further to offset losses on *inframarginal* units of insurance. Hence,

$$(6) \quad \left(\left. \frac{d\beta}{d\alpha} \right|_v \right)_\Omega = \left(\left. \frac{d\beta}{d\alpha} \right|_{ZPL} \right)_\Omega > q_\Omega$$

Since at Ω the slope of the indifference curve exceeds the price of insurance, individuals would like to acquire more insurance at the price q_Ω (see Pauly, 1974). Thus, competitive decentralization of Ω requires rationing of insurance at the price q_Ω .⁸ The intuition for this result is that, because of moral hazard, at any price of insurance, the individual expends too little effort. Rationing induces him to increase his effort. The easiest⁹ way for such rationing to be

but since more insurance causes the probability of accidents to rise, $p/(1-p)$ increases. The zero-profit locus is positively sloped for small amounts of insurance but may bend backwards.

⁸The point Ω can be decentralized by the insurer offering any locus of (α, β) such that Ω is the point of maximum utility on the locus and insisting that he be the sole insurer. One such possibility entails the insurer offering the zero-profit locus. This particular form of nonlinear pricing in this context was considered by Elhanan Helpman and Jean-Jacques Laffont (1975). The analysis of the paper carries through whatever form of pricing is employed to decentralize Ω .

⁹Insurers could alternatively agree to sell a client who has purchased a total amount of insurance from other insurers of (α', β') an insurance policy $(\hat{\alpha}, \hat{\beta}) = (\alpha_\Omega - \alpha', \beta_\Omega - \beta')$, which would bring his total insurance up to $(\alpha_\Omega, \beta_\Omega)$. However, this is unnecessarily complicated. In fact, almost all insurance policies contain exclusivity provisions (life and air-flight accident insurance are the exceptions, but moral hazard is unimportant for both types of insurance).

accomplished is for each insurer to offer the contract $(\alpha_\Omega, \beta_\Omega)$, conditional on its clients purchasing no additional insurance. This condition, which we term the exclusivity provision, is enforceable, since it is assumed that insurers are able to observe all insurance purchases.

To sum up, with moral hazard, when non-market insurance is absent and insurance purchases are observable, the social optimum conditional on the unobservability of effort is decentralizable. Competitive equilibrium entails each individual being restricted to purchase all his insurance from a single insurer and being rationed in the amount of insurance he can purchase at the equilibrium price.

II. Effort Unobservable by the Nonmarket Insurer

We now consider the simplest possible extension of this model that allows for the simultaneous provision of market and non-market insurance. We assume that, although an insurer can observe his clients' insurance purchases, he cannot observe the nonmarket insurance they acquire.¹⁰

As described earlier, nonmarket insurance may be provided through many institutions. To simplify, we treat only nonmarket insurance provided reciprocally by pairs of symmetrical individuals. We label the two partners in a pair, H (husband) and W (wife). The two partners have the same tastes and probability-of-accident functions, and their accident probabilities are statistically independent.¹¹ The form of the non-market insurance is as follows: H and W agree that if one spouse has an accident and

FIGURE 2. THE EFFECT OF NONMARKET INSURANCE WHEN IT REDUCES EFFORT

the other does not, the latter will transfer δ to the former.

The issues to be addressed can be posed in terms of Figure 2. The solid-lined ZPL and V_Ω are the zero-profit locus and equilibrium-indifference curve in the absence of nonmarket insurance (the same as in Fig. 1); the dashed-lined ZPL and V_Ω' are the corresponding curves with nonmarket insurance. Assume, for the sake of argument, that the provision of nonmarket insurance reduces effort. There are then two offsetting effects on equilibrium utility. On one hand, with α and β held fixed, the provision of nonmarket insurance increases utility; it shifts indifference curves to the left. On the other hand, since by assumption the provision of nonmarket insurance increases the probability of accident, the insurance firm must lower the payout for any level of the premium to continue making zero profits; as a result, the ZPL also shifts to the left. The analysis that follows examines which effect is dominant.

In this section, we characterize the equilibrium for the case in which an individual's accident-avoidance effort is observable by neither his partner nor market insurers. Equilibrium may entail a combination of market and nonmarket insurance. Subsequently, we shall investigate the efficiency properties of the equilibrium.

¹⁰If an insurer were able to observe the nonmarket insurance that his clients acquire, he could write the contract contingent on their nonmarket insurance. The resulting equilibrium would be efficient conditional on the information available (the efficiency result depends on there being only one commodity and one type of accident; see Arnott and Stiglitz, 1986, 1989).

¹¹This assumption simplifies the analysis and does not affect the qualitative results. Depending on context, the accident probabilities of the partners may be positively correlated.

There are four events: 1) neither the individual nor his partner has an accident; 2) the individual has an accident, but his partner does not; 3) only the partner has an accident; 4) both have accidents. Let e denote the individual's effort and \bar{e} his partner's. Then, the probability that neither the individual nor his partner has an accident is $[1 - p(e)][1 - p(\bar{e})]$ and similarly for the other events. We assume that the market insurer sells individual rather than group insurance policies¹² (i.e., he sells each partner a policy (α, β) ; if neither individual has an accident, each has to pay the market insurer the premium β , etc.).

Thus, an individual's expected utility is

$$(7) \quad EU = u(w - \beta)[1 - p(e)][1 - p(\bar{e})] \\ + u(w - d + \alpha)p(e)p(\bar{e}) \\ + u(w - \beta - \delta)[1 - p(e)]p(\bar{e}) \\ + u(w - d + \alpha + \delta)p(e) \\ \times [1 - p(\bar{e})] - e$$

which may be written more succinctly as

$$(7') \quad EU = u_0(1 - p)(1 - \bar{p}) + u_1 p \bar{p} \\ + u_2(1 - p)\bar{p} + u_3 p(1 - \bar{p}) - e$$

where $u_0 \equiv u(w - \beta)$, $u_1 \equiv u(w - d + \alpha)$, $u_2 \equiv u(w - \beta - \delta)$, $u_3 \equiv u(w - d + \alpha + \delta)$, and $\bar{p} \equiv p(\bar{e})$.

We assume that H and W are smart and take into account how the other will adjust effort in response to a change in δ .¹³ Both

assume that the market contract will be unaffected by their actions, which is perfectly reasonable in the atomistic environment we envisage.

We adopt the Nash assumption. W, in deciding on her level of effort, takes α , β , and δ as well as H's effort as fixed. W believes that H is rational and selfish and will accordingly choose the level of effort that maximizes his expected utility, given that W is acting similarly.¹⁴ Then, from (7), the equation characterizing her level of precaution is

$$(8) \quad [-u_0(1 - \bar{p}) + u_1 \bar{p} - u_2 \bar{p} \\ + u_3(1 - \bar{p})]p' - 1 = 0$$

which gives

$$(9a) \quad e = \hat{e}(\alpha, \beta, \delta, \bar{p})$$

and by symmetry

$$(9b) \quad \bar{e} = \hat{e}(\alpha, \beta, \delta, p).$$

Combining (9a) and (9b) yields

$$(10a) \quad e = e(\alpha, \beta, \delta)$$

$$(10b) \quad \bar{e} = e(\alpha, \beta, \delta).$$

From (7), the individual and his partner perceive expected utility to be related to δ in the following way:

$$(11) \quad \frac{\partial EU}{\partial \delta} = [-u_2'(1 - p)\bar{p} + u_3'p(1 - \bar{p})] \\ + \{[-u_0'(1 - \bar{p}) + u_1'\bar{p} - u_2'\bar{p} \\ + u_3'(1 - \bar{p})]p' - 1\} \frac{\partial e}{\partial \delta} \\ + [-u_0'(1 - p) + u_1'p \\ + u_2'(1 - p) - u_3'p] \bar{p}' \frac{\partial \bar{e}}{\partial \delta}.$$

¹²Where the insurance company cannot identify the nonmarket insurance partners (friends, for example), this is the natural assumption. However, in other contexts, notably the family, the market typically provides group policies. We have run through the analysis when the market provides group rather than individual policies. Group policies are Pareto-superior, since they contain an extra policy parameter: an insurance policy specifies the group premium payable if neither has an accident, the net payout if only one has an accident, and the net payout if both have an accident. In other respects, the qualitative results are the same when the market provides group policies as when it provides individual policies.

¹³We would obtain the same qualitative results if we assumed instead that H and W ignore that the other will adjust effort in response to a change in δ .

¹⁴This is not an infinitely repeated game. If it were, the cooperative outcome might be obtained. We comment on this later.

In so doing, they neglect that, since other couples too behave in this way, insurance companies adjust α and β in response to a change in δ . Combining (8), (10a), (10b), and (11), and noting that the equilibrium is symmetric, gives

$$(12) \quad \frac{\partial EU}{\partial \delta} = (-u'_2 + u'_3)(1-p)p + [1 + (u_2 - u_3)p'] \frac{\partial e}{\partial \delta}.$$

Furthermore, from (8),

$$(13) \quad \frac{\partial e}{\partial \delta} = - \frac{[u'_2 p + u'_3(1-p)]p'}{(p''/p') + (p')^2(u_0 + u_1 - u_2 - u_3)} < 0.$$

At Ω (the competitive equilibrium in the absence of nonmarket insurance), $\delta = 0$, $1 + (u_2 - u_3)p' = 0$ [from (8) since $u_0 = u_2$ and $u_1 = u_3$], and $-u'_2 + u'_3 > 0$ (incomplete insurance). Hence, from (12),

$$(14) \quad \left. \frac{\partial EU}{\partial \delta} \right|_{\Omega} = (-u'_2 + u'_3)(1-p)p > 0.$$

Thus, at the competitive equilibrium in the absence of nonmarket insurance, the partners perceive a mutual insurance pact to be beneficial and would therefore provide one another with nonmarket insurance to supplement their market insurance. The intuition for this result is as follows. At Ω , the partners are rationed in the amount of insurance they can purchase at the price q_{Ω} . Each perceives that, by entering into a mutual insurance pact, he can acquire additional insurance at this price, which pays out when he, but not his partner, suffers an accident. More specifically, at Ω , since

$$\frac{\partial EU}{\partial \alpha} = pu'_3 \quad \text{and} \quad \frac{\partial EU}{\partial \beta} = -(1-p)u'_2$$

from (12),

$$(15) \quad \frac{\partial EU}{\partial \delta} = (1-p) \frac{\partial EU}{\partial \alpha} + p \frac{\partial EU}{\partial \beta}.$$

An individual regards a unit increase in δ as equivalent to a unit increase in α with probability $1-p$ (the probability that his partner is not sick when he is) combined with a unit increase in β with probability p (the probability that his partner is sick when he is not), or equivalently, as an expected increase of $1-p$ in the amount of insurance obtained at the price q (i.e., movement from Ω to ϕ in Fig. 1). As already noted, in reasoning in this way, individuals neglect that, when everyone enters into such a pact, which reduces effort [eq. (13)] and increases the probability of accident, market insurers are forced to offer a less attractive contract in order to maintain zero profits.

H and W choose δ to maximize their expected utilities, taking α and β as given. From $\partial EU / \partial \delta = 0$, $e = \bar{e}$, and (8), one obtains $\delta = \delta(\alpha, \beta)$. By observing how the probability of accident responds to changes in α and β , market insurers will implicitly take into account that δ responds to α and β according to $\delta = \delta(\alpha, \beta)$. Competition, meanwhile, will continue to result in the equilibrium market contract maximizing expected utility subject to zero profits. Thus, in the presence of nonmarket insurance, the equilibrium market contract maximizes

$$(16) \quad \begin{aligned} EU = & u(w - \beta)(1-p)^2 \\ & + u(w - d + \alpha)p^2 \\ & + u(w - \beta - \delta)(1-p)p \\ & + u(w - d + \alpha + \delta)p(1-p) - e \end{aligned}$$

subject to

$$\begin{aligned} (i) \quad & \beta(1-p) - \alpha p = 0 \\ (ii) \quad & e = e(\alpha, \beta, \delta(\alpha, \beta)) \end{aligned}$$

where (ii) is obtained by combining (10a) and $\delta = \delta(\alpha, \beta)$.

Given the assumed information technology, it can be shown that the nonmarket insurance is unambiguously harmful and dysfunctional. The line of proof is straightforward: welfare is at least as high if the market insurer chooses α , β , and δ as if he chooses just α and β , with δ being chosen by the nonmarket insurer; and if the market

insurer chooses α , β , and δ , he will set $\delta = 0$.

The equilibrium without nonmarket insurance cannot be improved upon, and if it were possible, it would be desirable to outlaw the provision of nonmarket insurance. The intuitive rationale for this result is as follows. The provision of nonmarket insurance does not enhance the risk-sharing capabilities of the economy. Rather, such insurance crowds out market insurance. Not only is it less effective than market insurance since it randomizes an individual's event-contingent consumption and is provided by a risk-averse agent (see John M. Marshall, 1976), but also the simultaneous provision of market and nonmarket insurance violates exclusivity, which typically creates uninternalized externalities (see Arnott and Stiglitz, 1989).

The above analysis was predicated on the assumptions that a market which provides insurance against the accident in question exists and that there are no transaction costs associated with the provision of insurance. If market insurance against a given accident does not in fact exist, voluntary nonmarket insurance is unambiguously beneficial.¹⁵ When transactions costs are present, nonmarket insurance may be beneficial if it is provided at lower transaction cost than market insurance.

III. Effort Observable by the Nonmarket Insurer

This case is more interesting, since there appear to be two offsetting effects. On one hand, because individuals have information on their partner's effort, which an insurance company does not, the provision of nonmarket insurance has the potential of enhancing the risk-sharing capabilities of the economy. On the other hand, the provision of insurance by a risk-neutral agent is typically more efficient than provision by a risk-averse

agent, if they have access to the same information. Furthermore, the simultaneous provision of market and nonmarket insurance violates exclusivity. This line of reasoning suggests that the provision of nonmarket insurance in this case may be beneficial in some circumstances and harmful in others.

We continue with the same model. When effort is observable within the family but not to the insurance firm, and when, as we have assumed, individuals are identical, family members will effectively choose the level of precaution to take cooperatively. Each will take α and β to be fixed and choose δ and e to maximize

$$(17) \quad EU = u_0(1-p)^2 + u_1p^2 + u_2(1-p)p + u_3(1-p)p - e.$$

This yields the following first-order conditions:

$$(18a) \quad e: [-2(1-p)u_0 + 2pu_1 + (1-2p)(u_2 + u_3)]p' = 1$$

$$(18b) \quad \delta: (-u'_2 + u'_3)p(1-p) = 0.$$

Equation (18b) implies that

$$(18b') \quad \delta = \frac{d - \alpha - \beta}{2}.$$

Because the partners can observe each other's effort and treat α and β as fixed, they perceive there to be no moral-hazard problem associated with the insurance they provide and hence provide full insurance (or as full as possible). This stands in contrast to the previous section where, as a result of the inability of each partner to observe the other's effort, only partial nonmarket insurance was provided [see (12)].

The insurance firm effectively chooses α and β to maximize expected utility, subject to (18a), (18b), and the zero-profit constraint. The competitive equilibrium with nonmarket insurance is characterized by the constraints and first-order conditions of this program.

¹⁵Market insurance is generally unavailable for the multitudinous small (but cumulatively substantial) risks faced in everyday life. How nonmarket institutions handle such risks is an important and interesting question.

We now investigate the welfare properties of the equilibrium. To do this, we assume that the planner chooses α , β , and δ , knowing that individuals choose e according to (18a), which takes account of the fact that δ is chosen with effort observable, and subject to the break-even constraint on market insurance.

Substituting the zero-profit constraint into (17) gives

$$(19) \quad EU(\beta, \delta) = u(w - \beta)(1 - p)^2 \\ + u\left(w - d + \frac{\beta(1 - p)}{p}\right)p^2 \\ + u(w - \beta - \delta)p(1 - p) \\ + u\left(w - d + \frac{\beta(1 - p)}{p} + \delta\right) \\ \times p(1 - p) - e.$$

The corresponding first-order condition for δ [using (18a)] is

$$(20) \quad \frac{\partial EU}{\partial \delta} = (-u'_2 + u'_3)p(1 - p) \\ - \left(\beta u'_1 p' + \frac{\beta(1 - p)}{p} u'_3 p'\right) \frac{\partial e}{\partial \delta} = 0.$$

Using (18a) again,

$$(21) \quad \frac{\partial e}{\partial \delta} = \frac{(1 - 2p)(u'_3 - u'_2)}{\Delta}$$

where

$$\Delta = \frac{\beta p'}{p^2} [2pu'_1 + (1 - 2p)u'_3] \\ - 2p'(u_0 + u_1 - u_2 - u_3) - \frac{p''}{(p')^2}.$$

Substituting (21) into (20) gives

$$(20') \quad \frac{\partial EU}{\partial \delta} = \frac{(u'_3 - u'_2)}{\Delta} \\ \times \left[\beta u'_1 p' - 2p'p(1 - p) \right. \\ \times (u_0 + u_1 - u_2 - u_3) \\ \left. - \frac{p''}{(p')^2} p(1 - p) \right].$$

Both Δ and the expression in brackets are unambiguously negative, and hence $\partial EU / \partial \delta = 0$ if and only if $u'_3 = u'_2$ [i.e., iff $\delta = \delta^* \equiv (d - \alpha - \beta)/2$]. Furthermore, $u'_3 > u'_2$ for $\delta < \delta^*$ and $u'_3 < u'_2$ for $\delta > \delta^*$, and so δ^* is the utility-maximizing δ . Thus, when effort is observable by the nonmarket insurer, the equilibrium is constrained efficient.

Does the provision of nonmarket insurance in this case stimulate or discourage effort? To answer this, we hold α and β fixed and increase δ from 0 to $(d - \alpha - \beta)/2$. Though the increase in δ unambiguously reduces risk, it has an ambiguous effect on effort. The risk reduction, by itself, encourages a reduction in effort. However, as δ increases, individuals become less selfish in their choice of effort. From (21), the former effect dominates if $p < 1/2$, and the latter effect otherwise. In the normal case, $p < 1/2$, the trade-off illustrated in Figure 2 is present, but the direct utility-increasing effect of nonmarket insurance unambiguously dominates the effort-reducing effect.

We can draw together the results in the following inequalities:

$$(22) \quad EU^1 > EU^{NMO} > EU^M > EU^{NMU}$$

where EU^1 is expected utility in the first-best case (with effort observable to both market and nonmarket insurers), EU^{NMO} is expected utility with nonmarket insurance and with effort observable to the nonmarket insurer but not the market insurer, EU^M is expected utility with only market insurance

and with effort unobservable to the market insurer, and EU^{NMU} is expected utility with nonmarket insurance and with effort unobservable to both market and nonmarket insurer.

IV. Discussion

The above models were rather stark. Some discussion and interpretation will therefore be useful. The results of the two cases analyzed above lead naturally to the conjecture that, in intermediate situations in which nonmarket insurers observe their partners' effort imperfectly but better than the market insurer, an excessive amount of nonmarket insurance will be provided which may or may not be better than no nonmarket insurance at all. The analysis could be extended to compare the optimal and equilibrium numbers of members in a nonmarket insurance group; in a large group, there is greater diversification of risk but more imperfect observability.

We distinguished between the two cases treated on the basis of the observability of one partner's effort by the other. The essential difference between the two cases was, however, the severity of moral hazard within the partnership, and this depends on more than the observability of effort. Such factors as the duration of the partnership, the discount rate, the frequency of accidents, the severity of punishment for renegeing on an agreement, the power of reputation and social pressure, and nonmonetary rewards from cooperation, are also important.¹⁶

We provided a rather narrow interpretation of our model. Other interpretations are possible. A market insurer and his clients

can be replaced by a principal and his agents, and the partnerships (with some elaboration of the model) can be replaced by secondary markets.¹⁷

In the above analysis, we took the observability of one partner's accident-prevention effort by the other as exogenous and considered only the extreme cases of unobservability and perfect observability. As we noted earlier, the degree of observability depends on the indirect monitoring system—the means by which one partner observes the other's effort, as well as the incentives to do so. Furthermore, in a fuller analysis, the indirect monitoring system would be treated as endogenous. Indeed, how indirect monitoring systems develop in nonmarket insurance institutions is an exciting research topic, as is the more general issue of how principals should design indirect monitoring systems so as to mitigate the incentives problem.

There is widespread belief that when significant market failure occurs, there are strong incentives for nonmarket institutions to develop which go at least part of the way toward remedying the deficiency.¹⁸ This paper has provided a counterexample¹⁹ in

¹⁷One can develop a typology in terms of the primary and secondary insurance arrangements, each of which may be market or nonmarket. We have considered the case in which the primary insurance arrangement is a market and the secondary arrangement is a partnership. The case primary-market/secondary-market is an insurance market in which exclusivity cannot be enforced.

¹⁸In anthropology there is a functionalist tradition of long standing which attempts to explain social institutions (political, economic, sociological, cultural, and psychological) as functional adaptations to a society's environment or ecosystem. Functionalist theories differ in their degree of subtlety and sophistication and in their emphasis, but none seems to make a sharp distinction between equilibrium and optimum. In most theories, however, there seems to be a presumption that institutional adaptation to the environment is efficient. See Roger Keesing (1981) for an informative discussion of contemporary traditions in anthropology.

¹⁹In our example, with effort unobservable to nonmarket insurers, the market by itself is constrained Pareto-efficient. However, there is *perceived* market failure, and the nonmarket institution (the provision of supplementary nonmarket insurance) arises in response to this perceived market failure.

¹⁶Altruism is also a factor in nonanonymous relationships. In terms of the model, let EU be an individual's expected utility and \widetilde{EU} his partner's. The individual maximizes welfare $W = EU + \lambda \widetilde{EU}$, where $\lambda = 0$ corresponds to the selfish case, $\lambda = 1$ to balanced altruism, and $\lambda = \infty$ to selfless altruism. If both partners are equally altruistic and cooperate (the effort-observable case), the outcome is independent of the degree of altruism. If both partners are equally altruistic and do not cooperate (the effort unobservable case), effort increases with the degree of altruism.

which a nonmarket institution arises spontaneously (through the uncoordinated actions of atomistic agents), which is completely dysfunctional (has effects opposite to those intended).²⁰ In our stark model, though the market response to imperfect information (the rationing of insurance) did indeed give rise to a nonmarket response (nonmarket insurance), whether the nonmarket response was welfare-enhancing turned out to depend on whether the nonmarket institution was informationally advantaged relative to the market institution. Our example illustrates, in a vivid way, the functionalist fallacy: the fact that an institution (nonmarket insurance) has a clearly identifiable function (to improve risk-sharing by supplementing the rationed insurance provided by the market) does not mean, within a general equilibrium context, that it actually performs that function (indeed, in one case, the nonmarket insurance was completely dysfunctional). We speculate that the possible dysfunctionality of nonmarket institutions is a general phenomenon. This, too, is an interesting topic for future research.

In an expanded version of our model in which there are many kinds of accidents and many commodities, the market is not constrained Pareto-efficient; there is genuine potential market failure (Arnott and Stiglitz, 1989). Our result concerning the possible dysfunctionality of spontaneous nonmarket institutions carries over to this more realistic setting.

²⁰In one sense, this result should come as no surprise, since it is by now well recognized that, even in large economies, Nash equilibria are Pareto-efficient only under special circumstances. One of the great achievements of modern economics was to identify a special set of assumptions under which competitive economies are Pareto-efficient.

George Akerlof (1980) has argued that inefficient social customs may persist as Nash equilibria and that there can be an arbitrarily large set of social customs sustainable as Nash equilibria. The point in our paper is related but different. Akerlof considers the possible persistence of inefficient institutions but does not investigate how the institutions came into being. We show not only that an inefficient institution can persist, but also that it can arise spontaneously. Furthermore, while in the Akerlof model there are multiple equilibria of which some may be efficient, in our model there is a unique equilibrium.

V. Conclusion

In this paper we developed a simple moral-hazard model in which individuals have an incentive to supplement market insurance with nonmarket insurance that is unobservable to the market insurer. Whether this nonmarket insurance is socially beneficial depends on whether the nonmarket insurance partners can monitor each other's accident-prevention effort better than the market. In the extreme case in which the partners have no more information than the market, the nonmarket insurance is unambiguously harmful. The nonmarket insurance crowds out the market insurance and results in less risk-spreading; it is therefore completely dysfunctional. In the other extreme case, in which the partners can observe each other's accident-prevention effort perfectly, the nonmarket insurance is ameliorative, and the equilibrium is constrained efficient. The peer monitoring by the nonmarket insurers is effectively utilized to mitigate the moral hazard and to improve the risk-sharing capabilities of the economy.

The simple model raises two broad questions which go beyond the context of moral hazard in insurance markets. In what other situations may nonmarket institutions be dysfunctional? And how may the economy utilize peer-monitoring systems to improve efficiency?

A Theory of Inefficient Intrafirm Transactions

By JULIO J. ROTEMBERG*

I consider a model in which the threat of customer departures induces sellers to supply high-quality goods. Permanent attachment of buyer and seller such that transactions take place inside a firm raises the social cost of delivering high quality. Yet, such costly integration is often profitable, because prices exceed marginal cost at equilibria where market transactions provide high quality. This theory can rationalize the empirical finding that middle managers are averse to transactions between profit centers. (JEL 611)

Unrelated individuals work together within firms where relationships of authority mold individual behavior. At least since Ronald Coase (1937), economists have viewed the abandonment of the market implied by these relationships as a socially desirable adaptation.¹ Oliver Williamson (1985 p. 17), for instance, states: "This book advances the proposition that the economic institutions of capitalism have the main purpose of economizing on transactions costs." In this view, the routing of transactions inside firms raises profits together with social welfare.

In this paper, I follow Coase (1937) in that I assume that integration and the concomitant abandonment of market transactions occur only when this is privately profitable. However, because product market imperfections exist, their private profitability is consistent with lack of social desirability. When goods markets are distorted, firms generally earn rents. Thus, firms would willingly tolerate organizational inefficiencies if such inefficiencies help them capture these rents. Some of the economy's rents may be

thus dissipated, and this may help explain why conventional measurements of profits do not uncover much monopolistic conduct.

I focus on a situation in which it is difficult to ensure that the good bought by one agent from another is of high quality. Quality is something the buyer can recognize *ex post* but not something that can be stipulated in advance when the agents enter into contracts. As shown by Benjamin Klein and Keith Leffler (1981) spot markets deal well with this problem, at least when price exceeds marginal cost. Then, sellers in spot markets try hard to provide high quality for fear that customers will change suppliers whenever they have an unsatisfactory experience. Such fear only arises if the customer's future business leads to profits and if it is reasonable to suppose that the customer will indeed leave when he is dissatisfied.

Even when suppliers try hard to provide high-quality goods, the good will sometimes fall short of the customer's expectation. This is particularly true when quality refers not to a technical characteristic, but to the way the good is delivered. An example of this is the supplier's ability to alter delivery schedules and specifications to accommodate changes in the customer's needs.

As in Franklin Allen and Gerald Faulhaber (1988), quality can fall below expectation for two reasons. The first is temporary bad luck which makes it impossible for the supplier to accommodate the buyer in this particular instance. Such temporary bad luck bears no relationship to the likelihood that

*Sloan School of Management, Massachusetts Institute of Technology, Cambridge, MA 02139. the seller will offer high quality in the future. The second reason is that the supplier is sometimes genuinely incompetent. Then, he is likely to continue delivering bad quality in the future. A dissatisfied customer will typically not know whether he has faced bad luck or incompetence. Fearing the second possibility, he may well leave. As a result, the producer will indeed try to keep the customer happy.

Long-term contracts that penalize the buyer when he changes sellers reduce the incidence of these departures. This mobility is also reduced if the buyer and seller integrate and the managers of the integrated enterprise mandate internal transactions. Both of these approaches make it more difficult to ensure high quality. The seller is now less worried about losing his customer, so it is harder to induce him to improve quality.² In addition, both approaches make it more likely that the buyer will continue to purchase from a seller whose competence has declined. That long-term contracts and integration are at least sometimes associated with low quality should be apparent to those familiar with the food services at most American universities.

The evidence of Robert Eccles and Harrison White (1988) also suggests that low quality and internal transactions go hand in hand. They interviewed managers who buy and sell goods across profit centers in firms with multiple profit centers. The impression left by these interviews is that managers prefer external to internal transactions.³ They would rather buy from and sell to agents outside the firm. Internal transactions occur only when they are mandated by management. Frictions are much more common in these mandated transactions than in their external counterparts. Eccles and White justly regard their findings as a challenge to Williamson's (1985) view of firms. Their evidence suggests that transactions costs actually increase when firms engage in internal transactions.

²According to Coase (1988), he discusses this loss in quality from integration in his 1934 notes for his paper "A Theory of Contract."

³Much as university professors prefer to eat in establishments that are not run by their employer.

If long-term contracts and integration make quality more difficult to deliver, why do they arise? The reason is that delivery of high quality in spot markets requires that price exceed marginal cost. Reductions in mobility thus raise the combined profits of buyer and seller. When the buyer leaves, he starts paying rents to others. These rents are captured by tying the buyer to the seller.⁴

The paper proceeds as follows. Section I presents a variant of the Klein and Leffler (1981) model in which the actual level of quality is stochastic even when the supplier is trying hard to accommodate the buyer. For simplicity, I focus here only on the randomness introduced by temporary bad luck on the part of the seller. Section II presents an illustrative long-term contract. The contracts described in this section are generally efficient. They both provide a benchmark for the inefficiencies studied in later sections and illustrate the rent-capture advantages of reducing buyer mobility.

Section III focuses on inefficient outright integration of the buyer and seller. Here, I suppose that there is an alternative mechanism that can also improve quality. This more costly mechanism works even if there is no threat of customer departure. For instance, costly managerial attention might be able to ensure high quality by making seller infractions verifiable by outside agents. Alternatively, costly managers might be given a great deal of discretion which, as in Alchian and Demsetz (1972), allows them to induce the seller to perform some quality-enhancing tasks. Even this may not raise quality as much as the effort brought forth by spot markets. Because this mechanism has higher cost per unit of quality, it is socially inefficient. Nonetheless, the wedge between price and marginal cost may make integration with these features privately profitable.⁵

⁴For other models in which socially inefficient contracts arise because they help capture rents, see Philippe Aghion and Patrick Bolton (1987), Mathias Dewatripont (1988), and Janusz Ordover et al. (1990).

⁵The wasteful monitoring by managers of their suppliers appears to be similar to the wasteful monitoring of workers in Samuel Bowles (1985). There, managers waste resources monitoring to avoid having to pay

Section IV introduces imperfect competition which raises prices. With spot markets alone, such increases in price have a socially desirable result. They make it more likely that producers will supply high quality, because they now have more to lose when the customers depart. Unfortunately, these high prices do not diminish the benefits from integration or the benefits from signing a long-term contract that eliminates all buyer departures and has low quality. As a result, increases in prices raise the likelihood that long-term contracts and integration are inefficient relative to the spot-market outcome.

Section V focuses on a different inefficiency of equilibrium long-term contracts. This inefficiency arises when the aptitude of the seller varies stochastically. Because the seller sometimes becomes inept, the immediate departures of customers when they encounter bad quality are socially beneficial. They raise the average quality that customers receive. Nonetheless, long-term contracts that reduce buyer mobility and raise the likelihood of purchases from inept suppliers can raise profits, because price exceeds marginal cost. Section VI presents my conclusions.

I. Spot Markets in the Klein-Leffler Model with Free Entry

Sellers produce a homogeneous intermediate good. The marginal cost of a bad-quality version of the good is c . After spending

workers an efficiency wage (which represents an excess of the wage over the disutility of labor). Our papers differ not only in focus but also in structure. In Bowles's model, agent A wastefully monitors agent B to extract rents from B. Assuming that contracts can specify the level of monitoring, the contract between A and B is suboptimal for A and B taken together. Overall efficiency would be restored if B were allowed to pay A *ab initio* to refrain from monitoring.

By contrast, in my model, A and B benefit jointly from writing a contract that involves monitoring. They both benefit because their arrangement extracts rents from C, a third party who is not involved in the contract. This difference is partly responsible for the models' different conclusions. Whereas in my model firms grow too big, they need never grow larger than their minimum efficient scale in Bowles.

ε , the quality of the good sometimes improves. I assume that a particular item becomes a high-quality good with probability σ if the firm spends an additional ε on the item. With probability $1 - \sigma$, the quality of the item remains poor.

There are Y customers who are, each period, willing to pay up to r for one unit of low quality. They are willing to pay an additional μ for a unit of high quality. Customers are risk-neutral: they are willing to pay $r + x\mu$ for a unit which is of high quality with probability x .

Contracts cannot specify the level of quality. This incompleteness of contracts has several possible sources. One possibility is that outsiders are unable to observe quality, so that contracts stipulating payments as a function of quality are unenforceable. Another possibility is that quality is difficult to spell out when contracts are written, although buyer and seller both recognize it when goods change hands.

Therefore, the qualities of the good I am concerned with here are not easily measurable. Rather, they are things like courteous service and prompt handling of complaints. Another important quality attribute in which these problems arise is seller flexibility in meeting changes in the buyers needs. Consider the following. The buyer and seller originally write a contract for delivery at the beginning of December. The buyer then realizes that he would much prefer delivery in the middle of November. A high-quality seller is flexible, so that he is capable of changing the delivery at a low cost. A seller of bad quality finds it very costly to change the delivery date. The courts see only the *ex post* cost of changes in delivery terms and not the effort made in being flexible.⁶

In this section, I consider spot-market transactions in which the only payments are proportional to the number of items exchanged. Each purchasing transaction has three stages. First, all upstream suppliers announce their prices. Second, buyers choose sellers and agree to receive one unit at this price. Finally, delivery occurs either

⁶This example of quality is very reminiscent of Grossman and Hart (1986).

with low or high quality. Customers know what quality they have received, though not the quality received by others.⁷

Customers' beliefs about the quality they can expect to receive depend on the price charged and on their personal experience. There are different equilibria depending on the precise form of these beliefs. The worst equilibrium for suppliers has customers believing that goods are universally of bad quality. As long as $r \geq c$, there is then an equilibrium where all active suppliers charge c and provide bad quality. For a producer to deviate by providing either good quality or lower prices represents a simple gift to customers. For him to deviate by raising his price loses him all sales.

Equilibria with high quality have different beliefs and higher prices. At these equilibria, customers believe instead that essentially all producers who charge a relatively high price P try to provide high-quality goods. In equilibrium, various firms charge P and are initially regarded as identical. Customers thus pick their initial supplier at random.

If this supplier delivers high quality and continues to charge P , they come back to this supplier in the following period. By contrast, if he delivers low quality, they choose a supplier at random from among the other producers who charge P . The assumption that customers leave suppliers from whom they have received low quality while they stay with those whose quality has been good is crucial for supporting equilibria where quality is high. As will become clear below, if customers returned no matter what quality they received, there would be no incentive to provide high quality.

The only formal justification offered in this section for the departure of unsatisfied customers is their indifference among all suppliers. In practice, it seems reasonable to suppose that customers expect suppliers

who have failed to provide good quality to be worse than the average supplier. As a result, customers want to remain only with those suppliers whose quality has been high. I model this formally in Section V.

I now study the incentives to provide high quality at equilibria of this kind. In these equilibria, the value to a firm from having a single customer is V . By contrast, the value to a firm of a customer who is currently buying from another supplier is W . Therefore the value V equals

$$(1) \quad V = \max\{P - c - \varepsilon + \delta[\sigma V + (1 - \sigma)W], P - c + \delta W\}$$

where δ is the discount factor. The first expression in (1) is the value when the firm tries to provide high quality, while the second expression is the value when it decides to provide low quality. If the number of firms is finite, the value to a firm of a customer who is currently buying from another firm is proportional to V . The reason is that this customer can be expected to buy from the current firm sometime in the future. Therefore, W equals ξV , where ξ is smaller than 1 since, at best, the customer comes back after one period. If customers who switch pick their firm at random, this parameter goes to 0 as the number of firms goes to infinity. Let V^h and V^l denote the values of making and failing to make the effort to improve quality. Then, (1) implies

$$V^h = \frac{P - c - \varepsilon}{1 - \delta[\sigma + \xi(1 - \sigma)]}$$

$$V^l = \frac{P - c}{1 - \delta\xi}$$

Attempting to provide high quality is worthwhile if V^h exceeds V^l or

$$(2) \quad \varepsilon \leq \delta\sigma \frac{1 - \xi}{1 - \delta\xi} (P - c).$$

It is apparent from this expression that it becomes easier to sustain high-quality equi-

⁷Klein and Leffler (1981) let customers who have received bad quality communicate this to other potential buyers. These then desert the producer as well. This is less appealing if customers differ in their experiences with the producer.

libria as P becomes higher. In particular, because δ , σ , and $(1-\xi)/(1-\delta\xi)$ are each smaller than 1, high-quality goods are sold only if

$$(3) \quad P - c > \varepsilon$$

so that the firms make positive profits. Klein and Leffler (1981) and their followers have addressed what they regarded as the uncomfortable coexistence of these rents with free entry. Carl Shapiro (1983), for instance, argues that initial expenditures are necessary to establish a reputation for good quality and that the rents compensate the firm *ex post*. However, the model is equally consistent with free entry in the absence of such initial expenditures.

Free entry does prevent the equilibrium price P from exceeding c by more than $\sigma\mu$:

$$(4) \quad P - c \leq \sigma\mu.$$

Otherwise, a firm would enter, undercut the price by $\sigma\mu$, and sell low-quality goods to Y customers.

If customers expect low quality from firms that charge less than P , entrants who charge between P and $P - \sigma\mu$ get no customers, and condition (4) is the only restriction on price. Suppose instead that customers believe that any firm charging a price such that (2) holds tries to provide high quality. Such beliefs seem reasonable; firms that charge such prices will indeed try to provide high quality if customer desertions occur only in response to low quality. In the presence of such beliefs, (2) cannot hold as a strict inequality. Customers gravitate to entrants whose price makes (2) hold as an equality.

Now consider the incentives of a firm with attached buyers to charge a price different from P . If it raises its price above P , all customers will leave, and it will lose its usual profits. Moreover, its own benefit from reducing its price below P is no bigger than a new entrant's profit from undercutting P . The reason is that such cuts in P reduce revenues from the firm's attached customers. The requirement that firms with attached customers must have no incentive

to deviate from the price P thus imposes no additional restrictions.

Combining (2) and (4), equilibria with high quality exist only if

$$(5) \quad \varepsilon \leq \delta\sigma^2\mu \frac{1-\xi}{1-\delta\xi}.$$

From a social point of view, the effort to provide high quality is worthwhile if and only if

$$(6) \quad \varepsilon < \sigma\mu.$$

Otherwise the benefit from the effort $\sigma\mu$ is smaller than the cost ε . Because δ , σ , and $(1-\xi)/(1-\delta\xi)$ are each smaller than 1, (5) implies (6). When it is not socially worthwhile to make the effort, it will not be provided at any equilibrium with free entry. On the other hand, (6) does not imply (5). Condition (6) holds, while (5) is violated when

$$(7) \quad 1 < \frac{\sigma\mu}{\varepsilon} < \left(\frac{1-\delta\xi}{1-\xi} \right) \left(\frac{1}{\delta\sigma} \right).$$

Then, the effort to improve quality is socially worthwhile but not provided at an equilibrium with free entry. The region described by (7) disappears as δ and σ go to 1 and ξ goes to 0. Underprovision of quality (relative to the social optimum) becomes more likely as customers leave more often for accidental reasons (low σ), take longer in coming back (low δ), or come back even after having been disappointed (high ξ).

II. An Illustrative Long-Term Contract

In this section, I illustrate the advantages and disadvantages of a particular form of long-term association whose main purpose is to make separations less likely. I suppose that a single buyer-seller pair can write a long-term contract. Whatever contract this particular buyer-seller pair writes, the relationship of all other buyers with their seller is unaffected. The spot market considered in the previous section with price P continues to operate.

A general long-term contract has at least three elements. First, there is an initial transfer. Then, there is a payment \hat{P} to be made from the buyer to the seller in each period that the buyer requests a unit from the seller. Finally, there is a severance payment s that the buyer makes to the seller when he changes suppliers. For simplicity, I assume that ξ is essentially zero; once this payment has been made, the buyer never returns to the seller.

The contracts in the previous section can be put in this form by letting the firm charge the same price as the others and letting the severance payment equal 0. Buyers were then indifferent between staying with their current supplier and changing suppliers. This indifference allowed me to assume that buyers always stay when they receive good quality and always depart when they receive low quality. Here, I assume instead that the contract also stipulates the probability λ that the buyer stays after he receives low quality. While there is no mechanism that enforces that buyers leave with this probability, I ensure that they are willing to do so by choosing s so that they are indifferent between staying and leaving.⁸

Suppose that the contract is devised so that the seller tries to produce high quality. In this case, all sellers produce the same quality, so the buyer must be indifferent between the payment streams associated with different sellers. In particular, the buyer involved in the long-term contract must be indifferent between severing the relationship immediately and severing the relationship only after remaining with the seller for one more period. This implies that

$$s + \frac{P}{1-\delta} = \hat{P} + \delta \left(s + \frac{P}{1-\delta} \right)$$

or

$$(8) \quad s = \frac{\hat{P} - P}{1-\delta}$$

⁸Since the aim of the long-term contract is to keep the buyer and seller together, the probability that the buyer stays after receiving good quality remains 1. This also makes it easier to induce the seller to make the effort necessary to improve quality.

so the present discounted value of payments is the same whether the buyer stays with this particular seller or pays the severance payments and then buys at the price P .

Then, the value to the seller from having a currently attached buyer is

$$V = \max \{ \hat{P} - c - \varepsilon + \delta [(\sigma + (1-\sigma)\lambda)V + (1-\sigma)(1-\lambda)s], \\ \hat{P} - c + \delta [\lambda V + (1-\lambda)s] \}$$

Therefore, the values of trying to provide high quality and of providing only low quality are

$$(9) \quad V^h = \frac{\hat{P} - c - \varepsilon + \delta(1-\sigma)(1-\lambda)s}{1 - \delta[\sigma + (1-\sigma)\lambda]}$$

$$(10) \quad V^l = \frac{\hat{P} - c + \delta(1-\lambda)s}{1 - \delta\lambda}$$

Trying to provide high quality is profitable only if V^h is at least as large as V^l or

$$(11) \quad \varepsilon \leq \delta\sigma \left(\frac{1-\lambda}{1-\delta\lambda} \right) [\hat{P} - c - (1-\delta)s]$$

Substituting (8) in (11), the producer then actually tries to produce high quality if

$$(12) \quad \varepsilon \leq \delta\sigma \left(\frac{1-\lambda}{1-\delta\lambda} \right) (\hat{P} - c)$$

which is independent of s and \hat{P} . A one-dollar increase in s raises the present discounted value of payments if the buyer leaves by one dollar. To preserve the buyers indifference, the present discounted value of payments if the buyer stays forever must increase by one dollar as well. Similarly, seller indifference requires that a one-dollar increase in s (which reduces the payoff from trying to provide high quality) be matched by a one-dollar increase in the present discounted value of receipts if the buyer stays on. Therefore, as long as (8) is satisfied, the precise values of s and \hat{P} do not affect the provision of quality.

Raising s while ensuring that \hat{P} satisfies (8) has the same effect as raising the initial transfer from buyer to seller. Both make the seller better off at the expense of the buyer. For simplicity, I thus consider contracts in which s is 0. The resulting initial transfer, whose value does not affect the subsequent analysis, depends on the bargaining strength of the two agents. If the seller can make a take-it-or-leave-it offer which if rejected leads to the sequence of spot contracts, the transfer is 0. If, instead, the buyer can solicit offers from competing sellers, the transfer is negative.

A problem does arise if buyers can sign long-term contracts that give them large initial transfers not just initially but also at later points. Suppose a buyer believes that next period he can sign a long-term contract from which he receives so much initially that the total present value of his payments equals $(c + \varepsilon)/(1 - \delta)$. From the buyer's perspective, this is equivalent to having access to a price of $c + \varepsilon$ from next period on; but, with P equal to $c + \varepsilon$, it is obvious from (12) that it is impossible to provide high quality in the current period. Buyer access to future contracts on good terms makes it impossible to induce the seller to provide high quality now. For equilibria with high quality to exist, buyers must believe that those who offer good terms in the future will provide only low quality.

The right-hand side of (12) falls when λ rises. Indeed, it is equal to 0 for λ equal to 1. This means that higher values of λ make it more difficult to induce the sellers to provide high quality. The highest value for λ that is consistent with attempts to provide high quality makes (12) hold with equality and equals

$$(13) \quad \frac{\delta\sigma(P - c) - \varepsilon}{\delta\sigma(P - c) - \delta\varepsilon}$$

A higher value for λ would require a greater incentive to provide quality in the form of a higher \hat{P} or a lower s . However, either, of these changes would break the buyer's indifference and would result in immediate departure by the buyer.

There is an important case in which the maximal λ given by (13) is 0. This is the

case in which customers believe that any firm whose price satisfies (2) tries to provide high quality. Then, in equilibrium, (2) holds with equality, so (13) equals 0. Greater values of λ are possible only if there is slack in condition (2). Only then are firms so eager to try to provide high quality that they continue to do so even if dissatisfied customers sometimes remain.

The next question is the value to the buyer and seller of varying λ . I compute this value assuming, as before, that the initial bargaining between buyer and seller is efficient. Therefore, only the effect of λ on the sum of buyer and seller surplus is relevant.

When the buyer purchases from the seller, the two together obtain surplus equal to $r + \sigma\mu - c - \varepsilon$. With probability $\sigma + (1 - \sigma)\lambda$, the buyer returns the following period, and surplus in that period is again $r + \sigma\mu - c - \varepsilon$. With probability $(1 - \sigma) \times (1 - \lambda)$, the buyer leaves. He then receives a present discounted value of benefits equal to $(r + \sigma\mu - P)/(1 - \delta)$ from then on. Combining these terms, the present discounted value of the benefits to buyer and seller equals

$$(14) \quad \frac{r + \sigma\mu}{1 - \delta} - \frac{c + \varepsilon + \frac{\delta(1 - \lambda)(1 - \sigma)}{1 - \delta}P}{1 - \delta[\sigma + (1 - \sigma)\lambda]} \\ = \frac{r + \sigma\mu - P}{1 - \delta} + \frac{P - c - \varepsilon}{1 - \delta[\sigma + (1 - \sigma)\lambda]}$$

The first term in the final expression is the surplus the buyer gets when he makes all his purchases in the spot markets. Thus, the second term captures the benefits from the association. In each period that the buyer remains, these benefits equal the difference between P and the cost of production $(c + \varepsilon)$. Inequality (4) says that this difference is positive. This implies that expression (14) is increasing in λ . This is the basic problem. The buyer and seller benefit

from increases in λ because such increases capture rents from the other sellers who, collectively, get $P - c - \varepsilon$ when the buyer leaves. On the other hand, if λ rises too much, there is nothing that keeps the seller from offering bad quality.

Using the maximal value of λ in (13), this present value becomes

$$(15) \quad \frac{r + \sigma\mu - P}{1 - \delta} + \frac{(P - c - \varepsilon)[\sigma(P - c) - \varepsilon]}{(1 - \delta)[\sigma(P - c) - \sigma\varepsilon]} = \frac{r + \sigma\mu - c - \varepsilon/\sigma}{1 - \delta}.$$

There does exist an empirically implausible method for letting λ , and thus joint profits, be bigger without sacrificing quality. This method, which I ignore here, is to have the buyer and seller write a contract with a third party. Such a third party could receive payments from the buyer (and even from the seller) when the buyer changes suppliers. Such payments tend to assure the seller of the buyer's fidelity without encouraging the seller to reduce his quality. In the current setup, reductions in quality are encouraged by the severance payments s since these go to the seller. The problem with schemes involving payments to third parties is the obvious incentive that they create for collusion between the third party and the seller.

The contracts considered so far are as efficient as the outcomes with spot markets, since they have the same quality. Within this class of contracts, inefficiency would be present only if the long-term contracts led sellers to forgo high quality. Then, joint profits when the buyer purchases from the seller equal $r - c$ per period. After the buyer leaves the seller, his net profits have a present discounted value of $(r + \sigma\mu - P)/(1 - \delta)$. Since the buyer leaves with probability $1 - \lambda$ in each period, the present

value of joint profits equals

$$(16) \quad r - c + \delta \left[\left(\frac{\lambda}{1 - \delta\lambda} \right) (r - c) + \left(\frac{1 - \lambda}{1 - \delta\lambda} \right) \left(\frac{r + \sigma\mu - P}{1 - \delta} \right) \right] = \frac{r + \sigma\mu - P}{1 - \delta} + \frac{P - c - \sigma\mu}{1 - \delta\lambda}.$$

Increases in λ are worthwhile only when the price P exceeds $c + \sigma\mu$. Then, the buyer would prefer low quality at a price of c to paying P and getting high quality with probability σ . However, as I showed in Section I, free entry implies (4) and is thus inconsistent with this case. Inefficient long-term contracts in which low quality prevails cannot be optimal responses to high-quality spot-market equilibria with free entry. They can only be optimal responses if, as in Section IV, (4) is violated and the equilibrium price exceeds its maximum free-entry level.

In this section, I have illustrated the tension between rent capture and high quality. I have also shown that long-term contracts yield efficient outcomes relative to spot-market contracts when there is free entry. In the next three sections, I explore three inefficiencies relative to the spot-market outcome. The first comes from the existence of an alternative technology for providing high quality, the second comes from prices in excess of the free-entry level, and the third comes from random variations in the competence of the sellers.

III. Outright Integration

Outright integration differs from the sort of long-term contract I considered in Section II in that it changes the control rights of various agents. Integration is probably most easily thought of as involving a new agent who has (limited) authority over both the buyer and the seller. Hiring such an agent is attractive if he can improve the quality that is forthcoming when the buyer

and seller let λ equal 1. The seller and buyer would then keep all the rents this buyer would ultimately have paid to other sellers.

Suppose that the hiring of this agent at a cost of m per period ensures that the seller makes the requisite effort when he produces for a particular buyer. Assuming this payment only occurs when the customer buys from the seller, the present discounted value of the joint benefits equals

$$(17) \quad \frac{r + \sigma\mu - m - c - \varepsilon}{1 - \delta\lambda} + \delta \left(\frac{1 - \lambda}{1 - \delta\lambda} \right) \left(\frac{r + \sigma\mu - P}{1 - \delta} \right) \\ = \frac{r + \sigma\mu - P}{1 - \delta} + \frac{P - c - \varepsilon - m}{1 - \delta\lambda}.$$

This expression is maximized for λ equal to one if

$$(18) \quad P \geq c + \varepsilon + m.$$

Otherwise, the optimal λ is 0, and integration is not valuable. Integration is worthwhile only if the cost of the internally produced good, $c + \varepsilon + m$, is competitive with the price of the externally supplied version.⁹ When (18) holds, the maximized value of (17) is

$$(19) \quad \frac{r + \sigma\mu - c - \varepsilon - m}{1 - \delta}.$$

This value exceeds (15), the value of the best long-term contract that keeps the cost of the quality effort equal to ε , if

$$(20) \quad m < \frac{1 - \sigma}{\sigma} \varepsilon.$$

⁹With free entry, (4) holds, so (18) implies that $\sigma\mu \geq \varepsilon + m$. More generally, unless this condition holds, the buyer and seller together are better off forgoing quality altogether, rather than paying $\varepsilon + m$ for a benefit of $\sigma\mu$.

Condition (20) becomes easier to satisfy as σ becomes smaller. The reason is that when σ is low there are many separations, so that the rents captured by buyer and seller jointly when their contract has λ given by (13) are relatively low. Then, their collective rents can be increased substantially by letting λ equal 1 and spending m per period. By contrast, when σ is 1 (the original case in Klein and Leffler [1981]), condition (20) is violated for all strictly positive m . In this case, buyer and seller never need to separate in equilibrium, so that nothing is gained by forcing them to remain together.

The combination of (20) and (2), which is necessary for spot markets to involve high quality, implies that $\delta(P - c)$ exceeds $\varepsilon + m$. This in turn implies (17). Thus, for any σ strictly less than 1, there exist strictly positive m 's such that (20) holds, and if the spot market equilibrium has high quality, integration is privately desirable and socially inefficient. If vertical integration could somehow be eliminated, quality would be the same, and society would save m .

Up to now, I have interpreted m as a managerial cost which ensures that the effort of the seller (whose cost remains ε) is actually forthcoming. I now discuss informally some other possibilities; more formal treatment is postponed for future work. One possibility is that spending m renders the seller's exertion of effort verifiable by outsiders. For instance, the manager might record the seller's actions in a way that outsiders trust. Then, a contract that stipulates that the seller be paid ε if he actually incurs the requisite effort becomes enforceable.

Along similar lines, the expenditure of m might produce verifiable evidence not on the effort expended but on the quality that the buyer actually receives. Then, the manager could write a contract with the seller in which the payments to the seller depend on the quality received by the buyer. Suppose the seller receives c when quality proves to be low and $(c + \varepsilon)/\sigma$ when it proves to be high. As long as he is risk-neutral, he is now happy to exert the necessary effort, since he on average earns $c + \varepsilon$ when he does and c when he does not.

The role of top management in the preceding two paragraphs is to spend m collecting evidence on quality (or on the effort to supply quality). Management is the monitor as in Alchian and Demsetz (1972).¹⁰ One can also think of m rather differently. The cost m can represent a reduction in quality itself, rather than a managerial cost in obtaining the spot-markets outcome. In this interpretation, the integrated firm produces a good worth $r + \sigma\mu - m$, rather than $r + \sigma\mu$. Even more generally, m can represent any loss in utility for buyer and seller (relative to $\sigma\mu - \varepsilon$).

One particular form of this loss stressed by Eccles and White (1988) is the prevalence of conflict in integrated organizations. They suggest that conflict between buyer and seller within an organization is useful, because it helps management gather information. I now suggest a scenario in which such conflict is indeed useful. Suppose that, just before the good is produced, the buyer receives a signal. This signal tells the buyer which particular change in specification would increase buyer utility and by how much. The buyer would now like the seller to make the change. On the other hand, the seller finds any such change costly. Moreover, the seller knows something about the cost of the change that others do not know. Therefore, the seller would normally overstate the costs of the change, either to increase his compensation or to avoid the necessary effort. In the absence of any mediator between buyer and seller, the result would be costly bargaining.

The manager can now serve a useful role. He can be put in charge of deciding whether the change should be made.¹¹ To find out whether the change is worthwhile, he encourages buyer and seller to "fight." In this fight, both buyer and seller present evidence. They also suggest experiments for

the manager to carry out. Since the manager has complete control over the tools with which buyer and seller work, he can actually carry out these experiments and learn something about the cost and value of the change. This knowledge then guides his decision. Note that the knowledge acquired by the manager is unlikely to be perfect. Therefore, it is in the seller's best interest to pretend that his costs are high to the very end.

The upshot of all this could well be a gain to the buyer g_1 which is lower than $\sigma\mu$ and a cost to the seller g_2 which exceeds ε . In this case, m is given by $\sigma\mu - \varepsilon + g_2 - g_1$. As long as (17) and (20) are met, setting λ equal to 1 and hiring the arbiter-manager is worthwhile for the buyer and seller taken together. Alternatively, an arbiter-manager will find it worthwhile to hire both a buyer and a seller. This is a more appealing description, because it emphasizes that, in the integrated organization, the buyer and the seller are employees of the arbiter-manager.

Suppose that these buying and selling employees carry out both internal and external transactions. Which will they prefer? When the buying employee carries out an external transaction, he receives $\sigma\mu$ in direct utility. This is the utility that results from courteous service and flexible specifications. Both of these facilitate the job of the buying employee. By contrast, when the buying employee carries out an internal transaction, he receives only g_1 in direct utility. Similarly, the selling employee's disutility from an internal transaction, g_2 , exceeds that from an external one. It thus appears to be possible that, consistent with Eccles and White's (1988) empirical findings, both buyer and seller prefer outside transactions.

Whether buying and selling employees are averse to internal transactions obviously depends also on how compensation varies with the type of transactions that they carry out. If employees are heavily compensated every time they buy or sell internally, internal transactions will look good to them. Suppose in particular that the buying and selling employees own the integrated firm and keep its profits. Since integration raises profits, net of the utility costs of buyer and

¹⁰Their model assumes there is a technological reason for monitors. As a result, the monitoring that emerges is socially good. By contrast, the monitoring that takes place here could usefully be replaced by a market.

¹¹This arbiter role of management is also stressed by Williamson (1975).

seller, the two would then, prefer internal transactions.

Suppose that, on the contrary, the two are only employees and the profits go to a third party. Then, at least on average, buying and selling employees must be compensated for the disutility induced by internal transactions. This implication is at least consistent with the evidence that wages rise with establishment and company size (see Charles Brown and James Medoff, 1989). In the view of this paper, employees of larger (more integrated) companies must be paid a compensating differential because they have to transact disproportionately more with other employees of the same organization.

This does not mean, however, that employees will be paid a bonus in every instance when they carry out an internal transaction. As long as agents are risk-neutral, there is little reason for compensation to vary in this manner. From an administrative point of view, such micromanaging of compensation is probably burdensome, since it requires precise definitions of the extent to which a transaction is internal. Thus, organizations may opt for flat salaries that reflect the *typical* volume of internal transactions. With this compensation structure, employees get more utility from external transactions than from internal ones. For internal transactions to take place at all, they must then be mandated by management.

One issue that arises at this point is why the cost m must be spent within an organization that also includes the buyer and the seller. Why can't these resources be spent in an arms-length transaction? The answer is that, in the situation I have in mind, arms-length transactions need very little management and supervision. The threat of dissolving the relationship is sufficient to ensure considerable effort by the seller.

Still, why can't the buyer and seller write a long-term contract that binds them to each other and then spend m on the services of an outside party? There are two reasons. The first, and principal, reason is that monitoring, policing, and verification require power. The monitor must be able to change the conditions of production to find

out how the seller and buyer are actually behaving. This flexibility is essential precisely because it is difficult to predict in advance the form of the effort to provide quality. Therefore, the monitor must be in a position to dictate how the assets with which buyer and seller work are used. Such residual control over the use of assets virtually defines the role of top management. Indeed, from a legal point of view, such residual control is the purview of the owner of the asset.¹²

Second, familiarity with the buyer and seller helps in determining the cost of various quality-enhancing actions, as well as in verifying that these actions have been taken. Obtaining this familiarity takes time. There is thus a benefit to having the monitor remain in his job for a long time. By making the monitor part of the firm, his mobility costs increase, and he becomes more likely to learn the personal characteristics of buyer and seller.

The advantages of mergers that I describe are similar to those of the "incomplete contracts" theory of the firm surveyed by Holmstrom and Tirole (1987). As in that article, some individuals are put in charge, because contracts cannot specify all contingencies. These individuals get to decide how to proceed when the contract does not specify what is to follow.

Grossman and Hart (1986) also base their theory of the firm on contractual incompleteness. Yet, the implications of their model appear to be rather different from the one presented here. They focus on the contractual incompleteness that makes it difficult for individuals to garner the fruits of their human capital accumulation. In the absence of ownership rights, some of the benefits of an individual's human capital accumulation accrue to those he works with. Ownership can ameliorate this. The owner gets to decide on all aspects of the transaction not specifically contracted on in advance. As a result, he receives a disproportionate share of the payoff to both his and

¹²Grossman and Hart (1986) equate residual control over the use of assets with ownership.

his underlings human capital accumulation. Ownership of an asset by agent A alleviates the moral-hazard problem inherent in A's human capital accumulation (while worsening that of the other agents who work with this asset). They are careful to present their model as one of an owner-manager, though their theory perhaps applies also to corporate top management. In this case, one would expect top managers' compensation to be closely related to firm performance.

In my story, by contrast, moral hazard may not be an issue for top managers. Top managers are like policemen. The competence with which they dispatch these functions may be easy to determine from their reports. Top managers could still earn large sums if the skills needed to investigate whether the appropriate effort is being carried out are in short supply. In this case, one would expect larger firms, whose management problems are more complex, to hire more-competent monitors. This suggests that management compensation should increase with firm size. By contrast, their wages need not bear any particular relationship to firm performance. In practice, managerial compensation does seem more linked to firm size than to firm performance (see Michael Jensen and Kevin Murphy, 1988).

One critical question faced by all theories of the firm is the conundrum posed by Coase (1937) and Williamson (1985): what limits firm size? If top managers can intervene selectively and obtain whatever advantages there are to integration, a single firm should control the whole economy. This argument gains additional force when one recognizes that integration eases collusion in product markets.

Williamson (1985) gives a variety of reasons why managers cannot actually intervene so selectively. One reason that appears particularly germane in my context is that managers are imperfect and sometimes make mistakes. For managers to be effective at policing, they must have great authority, so these mistakes can be costly. They become more costly the larger is the manager's span of control. Giving a manager residual decision rights over the assets used by many individuals when his decisions only rarely

contribute to the common good is dangerous. By contrast, giving him these rights when intervention is needed often is more attractive.

IV. Imperfect Competition

Instead of letting entry be free, I assume here that the number of sellers is fixed at N . I show that the extent to which integration is inefficient can then depend on the level of rents in the industry.

Without free entry, price can exceed $c + \sigma\mu$. It can also exceed the level that makes (2) hold with equality even when customers view all firms whose price satisfies (2) as trying to provide good quality. To sustain such high prices, firms threaten each other with punishments as in James Friedman (1971). The worse the threatened punishment, the higher the prices that can be sustained in equilibrium. For concreteness, I focus on the worst possible punishments in the style of Dilip Abreu (1986). Similar results obviously obtain for weaker punishments.

The structure of the equilibrium is the following. Each firm is expected to charge P and earn a present discounted value of $\pi = Y(P - c - \varepsilon)/N(1 - \delta)$. A firm that deviates by raising its price loses all its customers, so this deviation is unattractive.

Suppose a firm deviates by cutting its price. Then, a punishment period ensues. All other firms charge $c + \varepsilon$ and try to provide high quality in the period after the deviation. In this period, the deviating firm is expected to charge a price L so low that its losses in that period equal $\delta\pi$. If firms charge these prices, they revert to charging P in the subsequent period. If any firm charges a different price, it is itself punished in analogous fashion.

Several comments about this construction are in order. First, all firms have an incentive to provide high quality if satisfied customers return in the following period, when the price is again equal to P . Second, the firm that is being punished can expect to earn a present value of 0 whether it charges L or not. If it does charge L its present discounted value of profits is 0 by construc-

tion. If it deviates and charges a higher price, customers expect its quality to be low, so that they are willing to pay at most c for its goods. This means that the deviating firm can do no better than charge c , break even in that period, and get punished again. This again gives it 0 in present value.

By cutting its price slightly below P , a firm can, at most, capture the entire market. Then, it would earn N times its usual per-period profits in the period of the deviation. After that, it earns a present value of 0. Thus, these deviations will not take place as long as

$$N \leq \frac{\delta}{1 - \delta}$$

which is independent of P and is satisfied for sufficiently high δ .

As in the case of free entry, there are both equilibria where quality is low and equilibria where quality is high. However, if (6) is met, switching from an equilibrium with low quality to one in which the firms try to supply high quality increases willingness to pay by more than it increases costs. Moreover, such a switch does not increase the equilibrium's vulnerability to deviations. Therefore, if the selling firms can pick equilibria and (6) is met, they will pick the equilibrium in which they produce high quality and charge $r + \sigma\mu$.

This ability of sellers to coordinate on equilibria with high prices is socially beneficial. It means that condition (2) becomes easier to meet, and firms find it in their interest to provide high quality. In particular, (2) can now be met even when (5) fails (so that free-entry equilibria have low quality). Moreover, in this model, there is no other distortion from high prices. With spot markets alone, their only effect on economic efficiency is to make high-quality equilibria possible in situations where, with free entry, only low-quality equilibria exist.¹³

¹³Contrast this with Michael Spence (1975), where monopoly (and thus collusion) generally distort quality away from the optimum.

I now study the effect of high prices on the attractiveness for one buyer-seller pair of both long-term contracts and outright integration. Consider first long-term contracts of the form considered in Section II. It is apparent from (14) that the derivative of joint profits with respect to λ rises with P . Higher prices make reductions in separations more attractive. As shown in (13), they also make higher values of λ feasible.

On the other hand, increases in P have a direct negative effect on the buyer. The net effect of these contradictory forces is that the joint profits at the optimal λ given by (15) are independent of P . The same is true of (16) with λ equal to 1, which gives joint profits if buyers and sellers forgo high quality altogether, and of (19), which gives joint profits under integration.

Therefore, the level of P itself has no effect on the choice of contractual form. However, it does affect the social optimality of the chosen contract. Suppose that ε is between $\sigma\mu$ and $\sigma^2\mu$ so that (5) is violated and market transactions in the presence of free entry involve low quality. If m is smaller than $\sigma\mu - \varepsilon$, buyer and seller will integrate. Relative to the spot-market outcome with free entry, this integration is efficient.

When ε is in this range, (6) is satisfied, so attempting to provide high quality is efficient. Moreover, if sellers with market power can coordinate, they choose a spot-market equilibrium with high prices in which quality is high; (16) with λ equal to 1 exceeds (15). Therefore, the contract with low quality, which avoids all separations, has higher joint profits than either spot-market transactions or any other contract of the form studied in Section II. If m is smaller than $\sigma\mu - \varepsilon$, joint profits are even higher under integration. However, both of these arrangements are socially less desirable than the spot-market equilibrium with high prices. Either they involve inefficiently low quality or inefficient integration.

The intuition for the result that the presence of market power reduces the efficiency of private contractual arrangements is the following. Market power raises prices, which makes the provision of high quality in spot markets easier. However, market power

does not reduce the private desirability of contractual forms where high quality, if it is provided at all, is costly.

V. Inefficient Separations with Long-Term Contracts

The long-term contracts of Section II feature fewer separations than the spot markets of Section I only because I have defined spot markets to have customers leave every time they encounter low quality. This definition of spot markets is, up to this point, arbitrary. If all producers are identical, customers ought to be indifferent among them. Thus, it is just as consistent with consumer maximization to assume that customers stay with a probability given by (13) when they have received low quality. This still ensures high quality and is identical to the long-term contracts of Section II.¹⁴ Another consequence of this indifference is that, at least with free entry, long-term contracts are just as socially efficient as what I have dubbed spot-market transactions.

In this section, I provide a reason for customers to leave when they encounter low quality. The reason is that low quality can mean two things. Either the seller has been temporarily unlucky (as I have assumed until now) or the low quality is an indication of seller incompetence.¹⁵ This possibility of seller incompetence makes buyers want to switch sellers whenever quality is low.

This possibility implies that long-term contracts that attach buyers to sellers are subject to a new form of inefficiency. This inefficiency is present even when sellers always try to provide high quality. It stems from the increased probability that buyers will purchase from incompetent sellers. In

spite of this inefficiency, such attachments can be privately optimal when price is high.

I suppose that firms can be in one of two states. In state w , they are well managed while in state b they are poorly managed. Poorly managed firms are intrinsically unable to provide high quality. They spend ε , and their quality is low nonetheless.¹⁶ The probability that a well managed firm remains well managed in the next period is $1 - \phi$. The probability that a poorly managed firm becomes well managed is $1 - \psi$. I assume that ψ exceeds ϕ , so that bad management has a tendency to persist. These transition probabilities imply a steady-state probability of being in state w equal to

$$(21) \quad \eta = \frac{1 - \psi}{1 + \phi - \psi}.$$

For simplicity, I also let the initial probability of being in state w equal η . Because $\psi > \phi$, η is smaller than the probability $1 - \phi$ that a previously well managed firm remains well managed.

Suppose that there is a spot-market equilibrium in which all firms charge P and in which well managed firms try to supply good quality. I first consider customer behavior, assuming such an equilibrium exists. I prove that customers come back to sellers who have given them high quality, while they desert those that have not. I then give conditions for this equilibrium to exist. These conditions ensure that well managed sellers do indeed try to provide high quality and that no seller wants to charge a different price.

Consider a customer who receives high quality in period t . He infers correctly that his current seller is well managed. His probability of obtaining high quality next period from this particular seller is thus $(1 - \phi)\sigma$. By contrast, his probability of obtaining high quality from a seller chosen at random is $\eta\sigma$, which is smaller. He therefore prefers to remain with his old seller.

¹⁴Of course, if customers stay with higher probability, equilibrium quality must be low.

¹⁵The presence of two analogous possibilities also induces customer departures in the monopoly model of Allen and Faulhaber (1988). Because they focus on the case with a single supplier, the possibility of seller incompetence plays a more crucial role. Without it, customers do not react at all to low-quality realizations, so that high quality is not sustainable in pure-strategy equilibria.

¹⁶Letting them avoid the cost ε changes the formulas below without affecting the qualitative results.

Suppose instead that the customer receives low quality at t . The posterior probability that he assigns to having a badly managed seller depends on his prior probability. This prior probability is lowest if the customer has bought a high-quality good from this particular seller at $t-1$, so that he knows the seller was well managed at $t-1$. I consider this case first.

Let w_t represent the event that the seller is well managed at t , b_t the event that he is poorly managed at t , and L_t the event that he provides low quality at t . Then, the probability of event w_t given that the seller was previously well managed and that he provides bad quality at t is

$$\begin{aligned}
 (22) \quad P(w_t | L_t, w_{t-1}) &= \frac{P(w_t, L_t | w_{t-1})}{P(b_t, L_t | w_{t-1}) + P(w_t, L_t | w_{t-1})} \\
 &= \frac{(1-\sigma)(1-\phi)}{\phi + (1-\sigma)(1-\phi)}.
 \end{aligned}$$

This probability is smaller than η as long as

$$(23) \quad \sigma \geq \frac{\psi - \phi}{1 - \phi}.$$

This condition is met as long as σ is sufficiently large. Then, well managed firms are sufficiently likely to deliver high quality that low quality is a signal of poor future prospects.

Now consider a buyer who has had no previous experience with this seller because he has just changed suppliers. His prior probability that the seller is well managed is then η . The posterior probability that he is well managed given that he has provided bad quality is

$$\begin{aligned}
 (24) \quad P(w_t | L_t) &= \frac{P(w_t, L_t)}{P(b_t, L_t) + P(w_t, L_t)} \\
 &= \frac{(1-\sigma)(1-\psi)}{\phi + (1-\sigma)(1-\psi)}.
 \end{aligned}$$

When ψ exceeds ϕ , this probability is smaller than η , so that customers who have just arrived leave suppliers who give them bad quality. In conclusion, when ψ exceeds ϕ and (23) is met, all buyers leave firms that offer low quality.

I now turn to seller behavior. I show that, given that consumers leave those who provide bad quality, sellers find it in their best interest to supply good quality. I later turn to sellers' incentives to change prices.

For simplicity, I assume again that ξ is zero, so that customers who leave essentially never return. Then, the value to a badly managed firm of an attached customer, who is about to leave, equals $P - c - \varepsilon$. Therefore, the value V to a well managed firm of having a customer is

$$\begin{aligned}
 V &= \max\{P - c - \varepsilon + \delta[\sigma(1-\phi)V \\
 &\quad + \phi(P - c - \varepsilon)], P - c\}.
 \end{aligned}$$

The values of trying to provide high quality and of providing only low quality are now

$$\begin{aligned}
 V^h &= \frac{(1+\delta\phi)(P - c - \varepsilon)}{1 - \delta\sigma(1-\phi)} \\
 V^l &= P - c
 \end{aligned}$$

so that trying to provide high quality is profitable if

$$(25) \quad \varepsilon \leq \frac{\delta[\sigma + \phi(1-\sigma)]}{1 + \delta\phi}(P - c).$$

As long as this modified version of (2) holds, well managed firms do not deviate by cutting quality.

For such prices to be equilibria with free entry, customers must prefer to pay P and receive high quality with probability $\eta\sigma$, rather than to pay c and receive low quality for sure. Thus,

$$(26) \quad P - c \leq \eta\sigma\mu.$$

For equilibria with high quality to exist when entry is free, prices must exist that satisfy both (25) and (26). In other words,

$\eta\sigma\mu$ must exceed

$$(1 + \delta\phi)\varepsilon / \delta[\sigma + \delta(1 - \sigma)].$$

If, in addition, customers believe that firms whose price satisfies (25) try to provide high quality, the unique equilibrium has (25) holding with equality.

The incentives of firms with attached customers to raise price above P are more complex in this case. The reason is that customers who have received high quality are willing to pay more to their current firm than the price charged by other firms. To simplify the exposition, I eliminate this scope. I do this by assuming that customers believe that any firm that charges a price different from P will produce low quality. Raising price then leads all customers to depart.¹⁷

Note that the analysis of Sections I, II, and III corresponds to the model of this section when one takes the limit as ϕ goes to zero. At this limit, the firm is almost always well managed, but if σ exceeds ψ , (23) is met, and the buyer leaves any firm whose quality proves low. Moreover, at this limit, the payoff from the long-term contracts described in Section II is well approximated by (14).

Suppose, however, that the system is not at this limit and that a certain buyer-seller pair is given the option of signing a long-term contract. Privately optimal long-term contracts are now more complex. The reason is that information about a seller's competence accumulates over time. A seller who has delivered bad quality for two periods in a row is more likely to be poorly managed than one who has delivered bad quality for only one period. These complications preclude the derivation of the privately optimal long-term contract in this paper. Rather, I focus on a very simple type of long-term contract, and I show that it will be attractive

to buyer and seller taken together even though it is socially harmful.

This simple contract applies only to the first period. If the buyer receives high quality in the first period, he stays as before. If, on the other hand, he receives low quality, he now remains with probability λ . Whatever the reason for staying, his behavior in subsequent periods is the same as his behavior with spot markets; he leaves any seller whose quality is low. Thus, the contract gives the initial seller only one "second chance." If he delivers low quality after that, he loses the buyer.

To focus on the new inefficiency, I ignore contracts in which sellers cease to make the effort necessary to improve quality. In other words, I consider contracts whose λ is sufficiently small that the seller continues to try to provide high quality. By continuity, positive λ 's that satisfy this condition exist when (25) and (26) are satisfied. This leaves open for further research the question of whether high quality is easier to sustain for a given λ when, as in this section, ϕ exceeds 0.

From the perspective of buyer and seller together, this contract has a cost and a benefit. The cost is that, if the seller is indeed incompetent in the first period, it is costly for the buyer to stay. The benefit is that, if the seller is only unlucky in the first period, the contract ensures the buyer-seller pair some surplus that would otherwise go to some other firm.

The contract only matters when the buyer receives low quality in the first period, as occurs with probability $1 - \eta\sigma$. In the absence of any contract, the buyer would then leave and obtain good quality with probability $\eta\sigma$ from his new supplier. His total payoff after the initial period would equal

$$(27) \quad \eta\sigma(r + \mu - P + \delta G) \\ + (1 - \eta\sigma)(r - P + \delta B)$$

where G and B represent the present discounted value of the buyer's payoff after having received good and bad quality respectively.

If the buyer stays after receiving low quality in the first period, he has a probability ν

¹⁷This feature could be avoided by focusing on equilibria in which new customers pay lower prices (introductory offers) than do customers that remain. The basic result is not sensitive to this change in specification.

of facing a well managed seller where:

$$\nu \equiv P(w_l|L_l)(1-\phi) + [1-P(w_l|L_l)](1-\psi).$$

This expression is smaller than η , because the firm that has delivered low quality is more likely to be badly managed than a firm chosen at random. If the buyer who remains pays P , his total payoff from remaining is

$$(28) \quad \nu\sigma(r + \mu - P + \delta G) \\ + (1-\nu\sigma)(r - P + \delta X).$$

Equation (28) is identical to (27), except that the probability of the good outcome is $\nu\sigma$ instead of $\eta\sigma$. For λ to be positive, the buyer must be indifferent between leaving and staying. Thus, if he leaves, the severance payment must equal the difference between (27) and (28).¹⁸

Ignoring the initial transfer, the buyer's total loss from the contract is the difference between (27) and (28) times the probability $\lambda(1-\eta\sigma)$:

$$(29) \quad \lambda(1-\eta\sigma)(\eta-\nu)\sigma[\mu + \delta(G-B)].$$

A tedious but straightforward calculation leads to a value for $G-B$:

$$G-B = \frac{\delta(1-\phi-\eta)\sigma\mu}{1-\delta\sigma(1-\phi-\eta)}.$$

Since $1-\phi-\eta$ lies between 0 and 1, this expression is positive and so is the value of (29). Note that the loss (29) is independent of P and that it vanishes as ϕ goes to 0 because, in this case, both η and ν go to 1. While I computed (29) as the loss the buyer

from the lower quality he receives on average, it also equals the social loss from the contract. The reason is that the total social costs of production are the same whether the buyer stays or leaves, so the change in consumer surplus (at unchanged prices) equals the change in total surplus.

The private gain from the contract is that the price P exceeds the cost of producing these goods. After giving the buyer bad quality, there is still a positive probability ν that the seller is well managed. If the buyer stays, the buyer-seller pair therefore gains $P-c-\varepsilon+\delta V^h$ with probability ν . With 1 minus this probability, they gain only $P-c-\varepsilon$. Total gains from the excess of price over cost are thus given by

$$(30) \quad \lambda(1-\eta\sigma)(P-c-\varepsilon+\nu\delta V^h).$$

This expression is positive and increasing in P . For P sufficiently high or ϕ sufficiently low, (30) exceeds (29) for strictly positive λ . Then, it is worthwhile to make λ positive, thus incurring the social cost (29) in exchange for the rents (30). While this only demonstrates the private advantages and social costs of a very special long-term contract, similar costs and benefits attend more general long-term contracts.

VI. Conclusion

Ever since Coase (1937), economists have generally viewed the internal organizations of capitalistic firms as benign. Even Williamson (1975, 1985), who feels that vertical integration sometimes reduces competition, asserts that the main purpose of integration and long-term contracts is to reduce "transactions costs."

This paper suggests a less sanguine view. Whether the organization of firms is socially helpful is an empirical question. It is not a question economists should feel capable of answering on a priori grounds alone. Since little other information on the actual functioning of these institutions exists, economists should pay close attention to the comments of managers and to their dislike of internal transactions.

¹⁸This computation assumes that the price that the buyer pays if he stays is the same as the external price. Increases in the price that the buyer pays if he stays must be matched one-for-one with increases in the severance payment to maintain buyer indifference. Increases in price must also be matched one-for-one to keep constant the seller's incentive to provide high quality. Thus, once again, the breakdown between the price the buyer must pay and the severance payment does not matter.

There may, of course, exist other reasons for this aversion. A partial explanation is that there exist specialized individuals (or organizations) with great skill. These individuals are efficiently utilized only when they serve a great many different customers, so that their integration with customers is worthwhile only in the case of very large customers. A relatively small firm then has a choice of integrating with a less competent individual (to the dismay of its buyers) or having an external transaction with one of the specialized individuals. This story explains the preference of buyers for outside partners but does not explain the analogous aversion of in-house sellers.

Perhaps managers dislike intrafirm transactions because they cloud managerial compensation. Insofar as transfer prices are somewhat arbitrary, wages that depend on profits reported by profit centers become risky as intrafirm transactions become more common. Holmstrom and Tirole (1987) explain GM managers' dislike of centralized procurement along analogous lines. This story is not complete. Firms must have some reason for exposing their employees to additional risk. In the case of GM, it seems plausible that centralized procurement allows GM to use its monopsony power more effectively. Rent capture may thus lie behind GM's move.

My model has several potentially testable implications. First, in many industries, firms that provide their own inputs coexist with others that obtain theirs in the open market. These differences must involve some heterogeneity; the cost m of carrying out transactions internally must vary across firms. Insofar as these differences in m are exogenous differences in transactions costs, my theory has the same implication as Coase (1937). Suppose instead that m is the cost from a given degree of quality deterioration. Then, my theory predicts that buyers who are more concerned with quality ought to be particularly averse to integration. This suggests that, controlling for all other observable characteristics, the producers of "high-end" products within an industry ought to be less integrated than the producers of "average" products.

Second, according to my theory, downward vertical integration should be more prevalent in industries in which price exceeds marginal cost by more. Along more standard lines, the increased incentive to integrate when prices are high may be attributed to the desire to avoid the "double marginalization" problem. However, unlike my theory, this standard motivation for vertical integration loses its force if agents are able to write complex contracts such as two-part tariffs.

The theory presented here may also be helpful in understanding why the organization of transactions differs across nations. Perhaps these organizational differences are due to cultural differences. In my model, buyer mobility is less important in nations where people find it culturally less acceptable to provide low quality. Therefore, my theory predicts that long-term attachments are prevalent where these transactions costs are low.

Another possibility is that these organizational differences can be traced to other differences in the production process. Perhaps, the Japanese *kanban* system inherently leads to higher quality because of its use of small batches. If this is interpreted as a high value for σ , my model would predict relatively little centralized control of the whole production process and relatively extensive attachment via long-term contracts. While this suggests some of the features of *keiretsu*, extensive investigation of the extent to which the model can explain international differences is left for further research.

Advertising in Competitive Markets

By MARK STEGEMAN *

In this paper, small firms sell a homogeneous good to small consumers under conditions of free entry, but consumers receive price information only through firms' advertising. In equilibrium, every firm on the continuous price distribution buys less advertising than is socially optimal. The result is robust if firms advertise in just one medium. If readers of different advertising media are positively correlated, excess advertising can occur in media used exclusively to advertise discount prices. (JEL 024, 026).

Critics portray advertising as a socially pointless attempt to capture market share through psychological manipulation. Others defend advertising by emphasizing its informative role. Identifying the purpose of advertising does not, however, resolve the underlying welfare question. Even purely informative advertising can be purchased to excess. The issues are complicated enough to make welfare results scarce, but George Stigler and Gary Becker (1977) and Len Nichols (1985) (henceforth, SBN) produce a striking result. They show that firms in competitive markets buy the socially optimal quantity of advertising.¹

The SBN result is important but less general than it first appears. In particular, SBN's advertising is not informative in the usual sense: every agent in the SBN model knows exactly what commodities and attributes are available, where, and at what prices, regardless of the level of advertising.

In other words, SBN's advertising increases demand not by resolving uncertainty or improving access to markets but, rather, by improving the attributes of already traded commodities. Such advertising is essentially *persuasive*.²

This paper reexamines the welfare question for purely *informative* advertising. The markets investigated are competitive in the sense that small firms sell a homogeneous product to small consumers, but all information about price and product availability flows through advertising. Advertising has no other purpose. In this setting, every firm advertises less than is socially optimal. The result is quite robust. If ads are homogeneous *ex ante* (i.e., ad campaigns of comparable size reach similar consumers, on average), then every firm underadvertises, regardless of the composition of the agents in the market and the advertising technology.

Certain circumstances can overturn the underadvertising result, but they appear to be rather limited in nature. Section III describes one possibility: if ads appear in diverse media and the readerships of these media are positively correlated, then firms

The comments of one referee improved the formulation of Proposition 1. The usual disclaimer applies.

¹Nicholas Kaldor (1950) and Peter Steiner (1966) present arguments against advertising. Lester Telser (1964) and Dean Worcester (1976) present arguments in its favor. Howard Beales et al. (1981) summarize the issues. Stigler and Becker (1977) emphasize the attribute model itself; Nichols (1985) emphasizes its welfare implications.

²Of course, it is possible that SBN's advertising improves commodity attributes by improving consumers' information. For instance, advertising may improve aspirin's attributes by telling consumers about new uses for aspirin. Nevertheless, this seems to be logically indistinguishable from what is normally called persuasive advertising. In either case, consumers get higher consumption value for an existing commodity; who can judge whether that value is "real" or "imaginary"?

may advertise too much in media used exclusively to advertise discount prices. Another possibility arises from consumer search. In this paper, consumers get all price information through advertising. Elsewhere I show that, if consumers also search for price information, then firms advertise too much if consumer search costs are sufficiently small (Stegeman, 1986, 1990). Despite these qualifications, the underadvertising result is robust enough to be interesting: competitive firms always underadvertise if all price information travels through a single advertising medium, and they tend to underadvertise in other cases.

The competitive model should serve as a starting point for the analysis of noncompetitive markets: markets having large firms, heterogeneous products, or barriers to entry. For instance, Stahl (1989) shows that large firms underadvertise in a symmetric mixed strategy equilibrium,³ and in Stegeman (1986) I show that small firms generically underadvertise in the standard circle model of product differentiation (e.g., Stephen Salop, 1979). These results are discussed in Section IV.

To put the present work in context, it is instructive to review the SBN model in greater detail. Following Lester Telser (1964), SBN assume that consumers obtain utility from attributes they consume. Advertising is an input that enhances the attributes of the final product and is thus an implicit argument in the utility function. If the number of firms in the economy is large relative to the number of attributes, then the markets for attributes may be effectively competitive, and the standard welfare result applies. Competition implies the efficient

use of all inputs, including advertising. SBN emphasize that the result requires competition in the implicit markets for attributes but not in the markets for commodities.⁴

SBN's optimal-advertising result rests on four strong assumptions. The first assumption, that attribute markets are effectively competitive, appears to be at least as strong as the assumption that commodity markets are competitive, since the world appears to have at least as many attributes as commodities. The second assumption is that advertising has no effects on persons who do not buy the product. Third, SBN intentionally exclude the possibility that advertising persuades consumers to buy goods that they should not buy. Not all economists agree that such irrational or compulsive behavior should be excluded from consideration. Fourth, SBN's advertising conveys no information about the terms of trade, because everyone knows the implicit price of every attribute regardless of the level of advertising.

This paper differs in the first and fourth assumptions. The difference in the first assumption is not crucial. Although this paper emphasizes competition in commodity markets and SBN emphasize competition in attribute markets, either model is consistent with competition in both commodity and attribute markets. The important difference lies in the fourth assumption.

In this paper, the only purpose of advertising is to allow each firm to announce its existence and price. The fraction of consumers who see at least one of the firm's ads is a continuous, strictly increasing, and strictly concave function of the quantity of ads sent. If the unit cost of advertising is constant, then it follows that the total cost of advertising is a convex function of the number of consumers reached.

Gerard Butters (1977) studies such an advertising technology and shows that its use implies the failure of the law of one price. The argument is that a firm advertising a price at a jump in the price distribu-

³Stahl's (1989) model is similar to the simplest (i.e., Section I) version of the present model, except that his firms enjoy economies of scale in advertising and his consumers have downward-sloping demand curves. His results apply only to symmetric mixed-strategy equilibria, unlike the asymmetric equilibria of the present model. Stahl also investigates the impact of changes in the numbers of firms and consumers. His paper and the present paper were developed independently. Most of the results in this paper appeared originally in Stegeman (1986).

⁴Richard Schmalensee (1972) and others have made somewhat similar arguments.

tion could obtain a nonnegligible increase in sales through an arbitrarily small price cut; therefore, the equilibrium price distribution must be continuous. The argument is quite general. The equilibrium price distributions in this paper are continuous for the same reason.

Returning to the welfare question, there is no obvious reason to expect Butters's firms to provide the socially optimal quantity of informative advertising. Butters shows that firms do advertise optimally in his model, but his assumptions are very restrictive, and he provides no intuitive explanation. Others have recognized the presence of opposing externalities. One externality, common in search models, exists because the benefits of search are divided between the searcher and the agent with whom he ultimately trades. Since the searcher (here the advertiser) bears the entire cost of search, he tends to search less than is socially optimal. A second externality occurs because a firm that advertises a low price draws sales and profits away from higher-priced firms. This "undercutting" externality tends to cause too much advertising. The exact cancellation of the two externalities in Butters's model is surprising. Grossman and Shapiro (1984) conjecture that the undercutting externality tends to dominate the search externality in homogeneous goods markets, causing excess advertising. The present paper shows, however, that the search externality generally dominates the undercutting externality, causing every firm to advertise less than is socially optimal. Butters's model is a limiting case of the models constructed in the present paper.

The paper is organized as follows: Section I shows that firms advertise less than is socially optimal in a simple model; Section II generalizes the model in several ways, and underadvertising persists in all cases; Section III shows that the availability of several advertising media may cause excess advertising in some media; Section IV summarizes related research into models of large firms and differentiated goods. All of the analysis is partial equilibrium, meaning that outside goods are implicitly assumed to be priced at marginal cost.

I. The Simple Model

The model in this section is similar to Butters's (1977) model, except that consumers have heterogeneous reservation values. A market opens once. On the supply side of the market, an unlimited quantity of firms produce a homogeneous good at constant unit cost c ($c \geq 0$). On the demand side, small (i.e., infinitesimal) consumers each want to buy one unit of the good. The "reservation value" of a consumer is the maximum price that he is willing to pay for the good; m is the maximum reservation value, and $\tau(v)$ is the fraction of consumers having reservation values less than or equal to v . Assume $m > c$, $\tau(c) = 0$, $\tau(v) < 1$ for $v < m$, and $\tau(v) = 1$ for $v \geq m$. Also assume that τ is continuous.

At the start of the (single) period, each firm must decide what price to advertise and how much advertising to send. A firm that advertises price p is called "firm p ." Firm p 's advertising simply announces that it sells the product at price p . The firm is subsequently required to honor its advertised price.⁵

To motivate the advertising technology, consider first a finite economy such that firms send discrete "ads," the demand side comprises n discrete consumers, and each consumer has $1/n$ chance of observing any given ad. Suppose that advertising is measured in "units" of ads per consumer. For any given block of A units of advertising (i.e., An ads), any given consumer observes none of the ads in that block with probability $(1 - 1/n)^{An}$. As n diverges to infinity, that probability converges to e^{-A} .

Advertising in the infinite economy is measured in "units" analogous to "ads per consumer." For any given block of A units of advertising, assume that any given consumer observes none of the ads in that block with probability e^{-A} . The cost of sending advertising is b per unit ($b > 0$). In equilibrium, firms collectively send a finite

⁵Arguments for honesty include loss of reputation and legal sanctions, but I include no explicit mechanism here.

positive quantity of advertising, but each individual firm sends zero units of advertising.⁶

Firm behavior is completely described by an advertising distribution $\alpha: [c, m] \rightarrow \mathbb{R}_+$; $\alpha(p)$ equals the units of advertising sent by firms charging prices less than or equal to p . After all ads have been sent, each consumer buys one unit of the good from the firm that sent the ad offering the lowest price among all the ads that the consumer observes, if that price does not exceed the consumer's reservation value. A consumer who observes no ads buys nothing. That completes the model. The exogenous parameters are b, c, m , and τ .

An equilibrium is defined to be a continuous advertising distribution $\alpha: [c, m] \rightarrow \mathbb{R}_+$, such that the return to the marginal ad is nonpositive at all prices and zero at every advertised price.⁷ To make that definition precise, let α denote an arbitrary continuous advertising distribution. Suppose that a firm p sends A additional units of advertising (creating a jump in the advertising distribution at price p). The additional units of advertising earn net profits

$$(1) \quad \pi(A; p, \alpha) \\ = (1 - e^{-A})e^{-\alpha(p)}[1 - \tau(p)] \\ \times (p - c) - bA.$$

The first term is the fraction of consumers who observe the new ads. The second term

is the fraction who do not observe lower-priced ads. The third term is the fraction who are willing to pay price p . The fourth term is the gross profit per unit sold. The product of the first four terms is the gross profit generated by the new ads. The last term is the cost of the ads. Given the advertising distribution α , the net profit from the marginal unit of advertising at price p is therefore

$$(2) \quad \mu(p; \alpha) \equiv \frac{\partial \pi(A; p, \alpha)}{\partial A} \Big|_{A=0} \\ = e^{-\alpha(p)}[1 - \tau(p)](p - c) - b.$$

Definition 1: $\alpha: [c, m] \rightarrow \mathbb{R}_+$, a nondecreasing function, is an equilibrium if

- (3a) $\alpha(c) = 0$
- (3b) $\mu(p; \alpha) \leq 0$ for all $p \in [c, m]$
- (3c) $\alpha(p_1) = \alpha(p_2)$
if $\mu(p; \alpha) < 0$ for all $p \in [p_1, p_2]$
- (3d) α is continuous.

The easiest way to show that an equilibrium exists is by construction. Let

$$(4) \quad \beta(c) \equiv 0 \\ \beta(p) \equiv \log \left(\frac{[1 - \tau(p)](p - c)}{b} \right) \\ \text{for } p \in (c, m].$$

Note that $\mu(p; \beta) = 0$ for all $p \in (c, m]$. Let

$$(5) \quad \gamma(p) \equiv \max_{s \in [c, p]} \beta(s) \quad \text{for } p \in [c, m].$$

Obviously, $\gamma: [c, m] \rightarrow \mathbb{R}$ is nondecreasing and satisfies (3a). For all $p \in [c, m]$, $\gamma(p) \geq \beta(p)$ implies $\mu(p; \gamma) \leq 0$, so γ satisfies (3b). Since γ is flat wherever $\gamma(p) \neq \beta(p)$ and is therefore flat wherever $\mu(p; \gamma) \neq 0$, γ satisfies (3c). Also, γ is flat in the neighborhood of c , and β is continuous everywhere else,

⁶Butters (1977) assumes that firms and consumers are finite in number and obtains all of his results in the limit as the numbers diverge to infinity. This approach requires some complicated technical arguments which Butters confines to an appendix. I avoid these complications by assuming from the start that firms and consumers are small. This implies that individual firms do not send positive quantities of advertising. One could assign a positive *density* of advertising to individual firms, but that is an inconvenient construction, because the density of advertising at any given price is indeterminate in equilibrium.

⁷The arguments of Butters (1977) and Kenneth Burdett and Kenneth Judd (1983) show that any equilibrium advertising distribution must be continuous. I avoid an elaborate restatement of those arguments and simply confine attention to continuous distributions.

so γ satisfies (3d). Therefore, γ is an equilibrium; γ happens to be the unique equilibrium, but that is not important for present purposes.

For an example of equilibrium, suppose that reservation values are distributed uniformly on the $[0, 1]$ interval and the unit cost of production is $c = 0$. If information were perfect, every consumer would purchase the good at the competitive price $p = 0$. Instead, suppose that firms must announce their prices through advertising and the unit cost of advertising is $b = 0.1$.⁸ Then, it is straightforward to show [using (5)] that firms advertise prices ranging from 0.11 to 0.50. Forty-eight percent of the consumers purchase the good, at an average price of 0.19.

The equilibrium γ has the curious feature that a mean-preserving spread of consumers' reservation values sometimes *shrinks* the range of advertised prices. For instance, if reservation prices are distributed uniformly on an interval $(M - \varepsilon, M + \varepsilon)$, where $M > c + b$ and ε is small, then (4) implies that β attains a maximum at $p = M - \varepsilon$, and (5) implies that advertising occurs at prices $p \in (c + b, M - \varepsilon)$. The range of advertised prices $(c + b, M - \varepsilon)$ is thus disjoint of the range of reservation values $(M - \varepsilon, M + \varepsilon)$. If ε increases slightly, then the interval of reservation values expands, forcing the interval of advertised prices to contract. It would be interesting to discover whether the inverse relationship between the spread of reservation values and the spread of prices is an

artifact of the example or a more general phenomenon, but that is beyond the scope of this paper.

For any advertising distribution $\alpha: [c, m] \rightarrow \mathbb{R}_+$ (continuous or not, equilibrium or not), the assumption that every consumer accepts the best offer at or below his reservation value implies that total welfare (i.e., surplus) equals

(6) $W(\alpha)$

$$\equiv \int_c^m (v - c)(1 - e^{-\alpha(v)}) d\tau(v) - b\alpha(m).$$

It is not immediately obvious whether firms advertise more or less than is socially optimal. Firms' inability to capture all consumer surplus (the search externality) tends to cause underadvertising, but the possibility of capturing profits from higher-priced firms (the undercutting externality) tends to cause excess advertising. Nevertheless, the search externality *always* dominates the undercutting externality. Increasing advertising at any advertised price increases welfare.

PROPOSITION 1: *Let α be an equilibrium advertising distribution such that $\alpha(m) > 0$. Let q denote the highest advertised price (i.e., q satisfies $\alpha(p) < \alpha(q) = \alpha(m)$ for all $p < q$).⁹ Let $h: [c, m] \rightarrow \mathbb{R}$ be any nondecreasing function such that $h(m) = h(q) > 0$. Then $W(\alpha + \varepsilon h) > W(\alpha)$ for sufficiently small $\varepsilon > 0$.*

PROOF:

First it shall be shown that $\mu(q; \alpha) = 0$ and $q < m$. If $\mu(q; \alpha) < 0$, then (3d) implies $\mu(p; \alpha) < 0$ for all $p \in [q - \delta, q]$ for some $\delta > 0$. Condition (3c) then implies $\alpha(q - \delta) = \alpha(q)$, a contradiction. Therefore, $\mu(q; \alpha) = 0$, and (2) implies $q < m$. Equation (6)

⁸This footnote shows that b can be interpreted as the marginal cost of reaching one additional consumer through advertising. Suppose that b is the cost of one unit of advertising in the n -consumer economy used to motivate the advertising technology. Since each unit of advertising comprises n ads, the marginal cost of reaching one more consumer is b/n . If each consumer's potential purchase is normalized to $1/n$, then the marginal cost of reaching $1/n$ more potential purchases is b/n . In the limit, the marginal cost of reaching potential purchases is b per potential purchase. If consumers are now renormalized so that each consumer makes one potential purchase, then b is the marginal cost of reaching one additional consumer through advertising.

⁹It is impossible to determine whether firm q actually exists (cf. footnote 6), but for expositional purposes it is convenient to assume that firm q does exist. The informal arguments based on the existence of firm q can all be reposed in terms of firms advertising prices in the neighborhood of q , which certainly do exist.

implies

$$\begin{aligned}
 & W(\alpha + \varepsilon h) \\
 &= \int_c^m (v - c)[1 - e^{-\alpha(v) - \varepsilon h(v)}] d\tau(v) \\
 &\quad - b\alpha(m) - b\varepsilon h(q) \\
 &\frac{\partial W(\alpha + \varepsilon h)}{\partial \varepsilon} \bigg|_{\varepsilon=0} \\
 &= \int_c^m (v - c)h(v) \cdot e^{-\alpha(v)} d\tau(v) - bh(q) \\
 &\geq \int_q^m (v - c)h(q) \cdot e^{-\alpha(q)} d\tau(v) - bh(q) \\
 &> h(q) \cdot \left[\int_q^m (q - c)e^{-\alpha(q)} d\tau(v) - b \right] \\
 &= h(q) \cdot \{(q - c)e^{-\alpha(q)}[1 - \tau(q)] - b\} \\
 &= h(q) \cdot \mu(q; \alpha) = 0.
 \end{aligned}$$

The intuition is as follows. Ads at prices in the neighborhood of m have a vanishingly small probability of being observed by a consumer who is willing to pay that price, so firms do not advertise prices in the neighborhood of m , implying $q < m$. Firm q captures no sales from other firms, and $q < m$ implies that it does not capture all the surplus from new sales it creates. Therefore, firm q has a socially inadequate incentive to advertise and could increase welfare by increasing its advertising. Therefore, any firm $p < q$ could increase welfare by increasing its advertising, because additional ads at prices $p < q$ increase total social surplus at least as much as additional ads at price q .

This line of reasoning avoids the problem of comparing the externalities directly. Only the search externality applies to the highest-priced firm, and the balance of the externalities for lower-priced firms is inferred indirectly from the argument that additional advertising at low prices must be

at least as good as additional advertising at high prices.¹⁰

Proposition 1 shows that every firm p can increase welfare by buying more advertising, but it does not follow that more advertising at every price p eventually leads to a globally optimal advertising distribution. A global optimum generally requires shifting advertising from high prices to low prices. Proposition 2 describes a global optimum in which c is the only advertised price. Firms lose money, but surplus is maximized because, for any given quantity of advertising, it is socially optimal to set the price of the good equal to its marginal cost of production. Proposition 2 shows that a globally optimal advertising distribution is $\eta: [c, m] \rightarrow \mathbb{R}$, where

$$(7) \quad \eta(p) \equiv \max(0, \log[(\bar{v} - c)/b])$$

for all $p \in [c, m]$

$$\bar{v} \equiv \int_c^m v d\tau(v)$$

(\bar{v} is consumers' mean reservation value).

PROPOSITION 2: $W(\eta) \geq W(\alpha)$ for all nondecreasing $\alpha: [c, m] \rightarrow \mathbb{R}_+$.

PROOF:

For any $A \geq 0$, let $\eta_A: [c, m] \rightarrow \mathbb{R}_+$ denote the ad distribution such that $\eta_A(p) = A$ for all $p \in [c, m]$. Equation (6) implies

$$W(\eta_A) = (1 - e^{-A})(\bar{v} - c) - bA.$$

¹⁰ It is not difficult to see at this point why every firm advertises exactly optimally in Butters's (1977) model. In Butters's model, all consumers have a common reservation value m , which must be the highest advertised price, since it is clearly suboptimal for the highest-priced firm to charge a lower price. Therefore, neither externality applies to the highest-priced firm, which consequently advertises exactly optimally. Since the marginal ad at any price below m creates the same number of aggregate sales and makes the same contribution to welfare, the marginal social return to ads at any price below m is also zero.

This function is strictly concave in A and is maximized at $A = \log[(\bar{v} - c)/b]$. For any nondecreasing $\alpha: [c, m] \rightarrow \mathbb{R}_+$, (6) implies

$$\begin{aligned} W(\eta_{\alpha(m)}) - W(\alpha) \\ = \int_c^m (v - c)[e^{-\alpha(v)} - e^{-\alpha(m)}] d\tau(v) \\ \geq 0. \end{aligned}$$

Therefore, $W(n) \geq W(\eta_{\alpha(m)}) \geq W(\alpha)$.

The welfare loss from suboptimal advertising is difficult to calculate. If reservation values are distributed uniformly on $[c, m]$, then I have shown in Stegeman (1986) that $W(\eta) - W(\alpha) < b/2$, where α denotes any equilibrium advertising distribution. $W(\eta) - W(\alpha)$ can be interpreted as the average welfare loss per consumer, and b can be interpreted as the average cost of reaching one consumer through advertising (cf. footnote 8).

II. Generalizations

This section generalizes the model in several ways. Every generalization preserves the competitive assumption that small agents are trading a homogeneous good, and every generalization but one preserves the assumption that all price information flows through a single advertising medium. Within these bounds, the underadvertising result is quite robust.

The first generalization is trivial. If firms have generally heterogeneous and nondecreasing marginal cost curves, then free entry implies that only firms producing at the lowest possible cost advertise in equilibrium; c denotes that cost.

A. Directed Advertising

In Section I, every consumer was equally likely to observe ads. In the present section, I divide consumers into a continuum of types, such that consumer's type determines his propensity to receive advertising and may be correlated with his reservation value.

It is still true that every firm underadvertises. The next two paragraphs sketch the argument. An interesting by-product of this analysis is the construction of a large family of advertising technologies, which may be useful in other applications.

Assume that consumers are divided into M types, where some types are more likely to observe advertising than others. Let j_m denote the fraction of consumers of type m ($\sum_{m=1}^M j_m = 1$). To set up the limit argument used in Section I, suppose for the moment that there are only n consumers and that each consumer of type m has k_m/n chance of observing any given ad. If a firm (or firms) sends A "ads per consumer" (i.e., An ads), then, as n diverges to infinity, the probability that a given consumer of type m observes none of those ads converges to $e^{-k_m A}$. The total fraction of consumers who observe at least one ad converges to

$$\begin{aligned} (8) \quad \psi(A) &\equiv 1 - j_1 e^{-k_1 A} - j_2 e^{-k_2 A} \dots \\ &\quad - j_M e^{-k_M A}. \end{aligned}$$

If M is large, then ψ can take a wide variety of shapes; each ψ can be interpreted as a distinct advertising technology. Butters's (1977) technology (also used in Section I) is the special case $\psi(A) = 1 - e^{-A}$. In every case, ψ is differentiable, strictly increasing, and strictly concave.

If a consumer's type is correlated with his reservation value, then $\psi(A)$ does not contain enough information to determine the equilibrium conditions. Therefore, $\psi(A)$ must be generalized to $\psi(v, A)$, where $\psi(v, A)$ denotes the fraction of consumers having reservation value v who observe at least one of the ads in any given block of A units of advertising. Assume that $\psi(v, A)$ is continuous in (v, A) , strictly increasing, strictly concave, and continuously differentiable in A , and that it satisfies $\psi(v, 0) = 0$ for all v . The general advertising technology $\psi(\cdot, \cdot)$ can then be transplanted into the model of Section I by substituting (1'), (2'),

and (6') for (1), (2), and (6).

$$(1') \quad \pi(A; p, \alpha) \equiv \int_p^m [\psi(v, \alpha(p) + A) - \psi(v, \alpha(p))] d\tau(v) \\ \times (p - c) - bA$$

$$(2') \quad \mu(p; \alpha) \\ \equiv \int_p^m \frac{\partial \psi(v, \alpha(p) + A)}{\partial A} \Big|_{A=0} d\tau(v) \\ \times (p - c) - b$$

$$(6') \quad W(\alpha) \equiv \int_c^m (v - c) \psi(v, \alpha(v)) d\tau(v) \\ - b\alpha(m).$$

Given these substitutions, the definition of equilibrium and the statement of Proposition 1 are unchanged. The proof of Proposition 1 is similar to the original proof.¹¹ Every firm advertises less than is socially optimal.

Directed advertising is interesting partly because it generates a large family of advertising technologies corresponding to various specifications of $\psi(v, A)$. For convenience, call this the exponential family. Butters's (1977) technology is just one member of the exponential family. This section has shown that Proposition 1 extends to every member of the exponential family.

Advertising technologies in the exponential family share two special properties. First, they exhibit no economies to scale. This is necessary in competitive models to ensure that firms are small. Second, the formulation of ψ [equation (8)] presupposes that ads are homogeneous. Section III investigates the consequences of heterogeneous ads.

B. Nonrectangular Demand Curves

Every consumer had a rectangular demand curve in section I, but the underadvertising result does not depend on that assumption. The argument follows. Suppose that consumers have generally heterogeneous demands and that total demand is strictly decreasing as a function of price. In equilibrium, some consumers must be willing to pay a price higher than q (the highest advertised price) for some units of the good, because otherwise firm q would lose money (cf. footnote 9). The marginal ad from firm q creates sales to consumers in that group who receive no other ads, but firm q does not capture all of the consumer surplus from such sales. Thus, firm q underadvertises. Therefore every firm underadvertises, since the marginal ad from firm $p < q$ increases total welfare at least as much as the marginal ad from firm q .

C. Communication Among Consumers

The model of Section I assumed that each consumer receives information only from the advertisements he observes. Instead, suppose that consumers share information. If each ad is passed on to several randomly chosen consumers, and each ad is passed on to the same expected number of consumers, then the revised model is equivalent to the original model with a lower cost of advertising b , and Proposition 1 is unchanged.

Alternatively, if lower-priced ads are passed around more than higher-priced ads, then the argument that welfare could be increased by sending more ads at price q is unchanged, and the argument that sending more ads at $p < q$ increases welfare at least as much as sending more ads at price q is reinforced. It is still true that every firm underadvertises.

To summarize, Section II has shown that Proposition 1 is quite robust. The conclusion that firms underadvertise is sensitive neither to the advertising technology nor to the market participants, which may be generally heterogeneous. Underadvertising also

¹¹The assumed properties of ψ ensure the continuity of μ in p , which implies $q < m$. The rest of the proof is a direct extension of the proof of Proposition 1, if one remembers that $\alpha(p) = \alpha(q)$ for all $p \in [q, m]$.

extends to models incorporating certain kinds of information exchange among consumers.

III. Several Advertising Media

In Section I, ads were homogeneous, in the sense that any given consumer was equally likely to observe any ad. This section describes a market in which firms can advertise in several different media, which tend to reach different classes of consumers. One medium might be particularly good for reaching consumers with high reservation values, and another might be good for reaching consumers with low reservation values. It will be shown that underadvertising must occur in some media but that excess advertising may occur in others.

An equilibrium in a model of M media is (extending the definition of Section I) a set of continuous advertising distributions, $\alpha_i: [c, m] \rightarrow \mathbb{R}_+$, $i = 1, 2, \dots, M$, such that the return to the marginal ad in medium i is nonpositive everywhere and zero at any price at which firms advertise in medium i , for all i . A more formal definition is not essential for most of what follows. It is useful, however, to distinguish two kinds of media in equilibrium. For a given equilibrium, let q_i denote the highest price charged in medium i [i.e., q_i satisfies $\alpha_i(p) < \alpha_i(q_i) = \alpha_i(m)$ for all $p < q_i$], and let $q \equiv \max_i q_i$ be the highest price advertised (cf. footnote 9). The medium or media used by the highest-priced firms (i.e., the media i such that $q_i = q$) are *full-price* media. Other media are *discount* media.¹²

A. Full-Price Media

The underadvertising result extends to full-price media. In other words, every firm underadvertises in every full-price medium.

The reasoning is similar (once again) to the reasoning behind the original Proposition 1. Firm q advertises only in full-price media and must be advertising less than is socially optimal in those media, because the marginal ad from firm q takes no sales from other firms and captures only part of the surplus from sales it creates. Any firm $p < q$ must also be advertising less than is socially optimal in every full-price medium, because ads at prices $p < q$ create at least as many new sales as ads at price q (in the same medium). Therefore, every firm underadvertises in every full-price medium.

The extension of Proposition 1 to all full-price media has interesting implications. For example, suppose that all advertising occurs in newspapers. If different consumers read different newspapers and advertising rates vary by newspaper, then distinct newspapers must be considered distinct media, and Proposition 1 does not apply. If, however, the highest-priced firms advertise in every newspaper, then all of the media are full-price media, implying that every firm underadvertises in every newspaper.

B. Excess Advertising in Discount Media

This section shows that Proposition 1 does not extend to discount media, by constructing an example of excess advertising in a discount medium. The example has the following general features. Firms can advertise in two media, D and F. Medium D is better than medium F for reaching low-reservation-value consumers, and medium F is better for reaching high-reservation-value consumers. In equilibrium, medium D becomes a discount medium, and medium F becomes a full-price medium. Medium D also reaches some high-reservation-value consumers and, in particular, reaches those who are also most likely to observe ads in medium F. The firms advertising the highest prices in medium D thus capture some sales from higher-priced firms advertising in medium F, and this negative externality is so strong that the former firms advertise too much in medium D.

To make the point more concrete, suppose that reservation values are correlated

¹² Whether a medium is a full-price or discount medium is determined in equilibrium. If there were multiple equilibria, then it is conceivable that a discount medium in one equilibrium could be a full-price medium in another equilibrium.

with wealth and that the *Times* is relatively better for reaching wealthy consumers than the *Post*. The essential characteristic of the example is that there exists a positive correlation between *Times* readers and *Post* readers among wealthy consumers, meaning that the wealthy population tends to divide into readers versus nonreaders rather than into *Times* readers versus *Post* readers. Then the firms advertising the highest prices in the *Post* capture so many sales from even-higher-priced firms advertising in the *Times* that the marginal social product of their advertising is negative.

The remainder of this section describes the particulars of the example. Assume that all firms produce the good at constant unit cost c ($c \geq 0$). Consumers are divided equally into three types. Type s has reservation value s , and types m_1 and m_2 have reservation value m ($m > s > c$). Firms have access to two advertising media (D and F). A consumer of type s has $1 - e^{-A}$ chance of observing at least one ad in any given block of A ads in medium D and does not observe ads in medium F. A consumer of type m_1 does not observe ads in medium D and has $1 - e^{-kA}$ chance of observing at least one ad in any given block of A ads in medium F, where k ($0 < k < 1$) is exogenous. A consumer of type m_2 has $1 - e^{-A}$ chance of observing at least one ad in any given block of A ads, regardless of the medium. Type m_1 consumers are (relative) nonreaders; type m_2 consumers are readers. The cost of advertising in either medium is b per unit ($b > 0$). The timing of the model is the same as in Section I. Each firm chooses a price and decides how much advertising to send in each medium. After all advertising has been sent, each consumer purchases one unit of the good from the firm charging the lowest price among the ads that he observes, if that price does not exceed his reservation value. The exogenous parameters of the example are b , c , s , m , and k . Assume that $s > c + b/2k$.

The next paragraphs provide a precise definition of equilibrium for the two-media model, describe a particular equilibrium (ϕ, δ) , define welfare for the two-media model, and show that excess advertising oc-

curs in medium D in equilibrium (ϕ, δ) . The definition of equilibrium is similar to Definition 1. Let α_D and α_F denote continuous advertising distributions in media D and F, respectively. A additional units of advertising at price p in medium D yield net additional profits

$$\begin{aligned} (9) \quad \pi_D(A; p, \alpha_D, \alpha_F) \\ &= (1 - e^{-A})e^{-\alpha_D(p)}(p - c) \\ &\quad + (1 - e^{-A})e^{-\alpha_D(p) - \alpha_F(p)} \\ &\quad \times (p - c) - bA. \end{aligned}$$

The first term is profit from sales to consumers of type s . The second term is profit from sales to consumers of type m_2 . A additional units of advertising at price p in medium F yield net profits

$$\begin{aligned} (10) \quad \pi_F(A; p, \alpha_D, \alpha_F) \\ &= (1 - e^{-kA})e^{-k\alpha_F(p)}(p - c) \\ &\quad + (1 - e^{-A})e^{-\alpha_D(p) - \alpha_F(p)} \\ &\quad \times (p - c) - bA. \end{aligned}$$

The first term is profit from sales to consumers of type m_1 . The second term is profit from sales to consumers of type m_2 . The expected profits from the *marginal* ad at price p [cf. (2)] in media D and F, respectively, are

$$\begin{aligned} (11a) \quad \mu_D(p; \alpha_D, \alpha_F) \\ &= (e^{-\alpha_D(p)} + e^{-\alpha_D(p) - \alpha_F(p)}) \\ &\quad \times (p - c) - b \\ (11b) \quad \mu_F(p; \alpha_D, \alpha_F) \\ &= (ke^{-k\alpha_F(p)} + e^{-\alpha_D(p) - \alpha_F(p)}) \\ &\quad \times (p - c) - b. \end{aligned}$$

Firms charging prices $p > s$ obviously do not use medium D in equilibrium, because medium F is just as good for reaching type-

m_2 consumers and better for reaching type- m_1 consumers. The following definition of equilibrium incorporates this observation.

Definition 2: An equilibrium (in the two-media example) is a pair of nondecreasing functions, $\alpha_D: [c, s] \rightarrow \mathbb{R}_+$ and $\alpha_F: [c, m] \rightarrow \mathbb{R}_+$, that satisfy (12a)–(12d) for $i = D, F$.

$$(12a) \quad \alpha_i(c) = 0$$

$$(12b) \quad \mu_D(p; \alpha_D, \alpha_F) \leq 0 \quad \text{for all } p \in [c, s]$$

$$\mu_F(p; \alpha_D, \alpha_F) \leq 0 \quad \text{for all } p \in [c, m]$$

$$(12c) \quad \alpha_i(p_1) = \alpha_i(p_2)$$

$$\text{if } \mu_i(p; \alpha_D, \alpha_F) < 0 \quad \text{for all } p \in [p_1, p_2]$$

$$(12d) \quad \alpha_i \text{ is continuous.}$$

Lemma 1 describes a particular equilibrium. In this equilibrium, firms charging prices in the interval $[c + b/2, s]$ advertise in medium D and firms charging prices in the overlapping interval $[c + b/2k, m]$ advertise in medium F. The advertising distribution for medium F is ϕ , where

$$(13) \quad \phi(p) \equiv 0 \quad \text{for } p \in [c, c + b/2k]$$

$$\phi(p) \equiv f^{-1}(0) \quad \text{for } p \in (c + b/2k, s]$$

$$\phi(p) \equiv g^{-1}(0) \quad \text{for } p \in (s, m]$$

where

$$f(x) \equiv ke^{-kx}(1 + e^{-x})(p - c) - b$$

and

$$g(x) \equiv ke^{-kx}(1 + e^{-k\phi(s) - (1-k)x}) \\ \times (p - c) - b.$$

Note that $f^{-1}(0)$ and $g^{-1}(0)$ are well-defined because f and g are monotonically decreasing and map \mathbb{R} onto $(-b, +\infty)$. The distribution of advertising in medium D is

δ , where

$$(14) \quad \delta(p) \equiv 0 \quad \text{for } p \in [c, c + b/2]$$

$$\delta(p) \equiv \log[2(p - c)/b] \\ \text{for } p \in (c + b/2, c + b/2k]$$

$$\delta(p) \equiv k\phi(p) - \log(k) \\ \text{for } p \in (c + b/2k, s].$$

LEMMA 1: (δ, ϕ) is an equilibrium.

PROOF:

It is straightforward to show that δ and ϕ are continuous and nondecreasing and that they satisfy $\delta(c) = \phi(c) = 0$. Direct substitution shows: $\mu_D(p; \delta, \phi) \leq 0$ for all $p \in [c, c + b/2]$; $\mu_D(p; \delta, \phi) = 0$ for all $p \in [c + b/2, s]$; $\mu_F(p; \delta, \phi) \leq 0$ for all $p \in [c, c + b/2k]$; $\mu_F(p; \delta, \phi) = 0$ for all $p \in [c + b/2k, m]$. Therefore, (δ, ϕ) also satisfies (12b) and (12c).

The next step is to define welfare in the two-media model. For any given pair of advertising distributions α_D and α_F , the assumption that every consumer accepts the best offer at or below his reservation value implies that total welfare (i.e., surplus) equals

$$(15) \quad W(\alpha_D, \alpha_F) \\ \equiv (1 - e^{-\alpha_D(s)})(s - c) \\ + (1 - e^{-k\alpha_F(m)})(m - c) \\ + (1 - e^{-\alpha_D(s) - \alpha_F(m)})(m - c) \\ - b[\alpha_D(s) + \alpha_F(m)].$$

The first three terms are the surplus from sales to consumers of types s , m_1 , and m_2 , respectively, and the fourth term is the total cost of advertising.

Proposition 3 shows that firms advertise too much in medium D in equilibrium (ϕ, δ) .

PROPOSITION 3: Let $h: [c, s] \rightarrow \mathbb{R}_+$ be any nondecreasing function such that $h(c) = 0$, $h(s) > 0$, and $\delta - h$ is nondecreasing. Then, $W(\delta - \varepsilon h, \phi) > W(\delta, \phi)$ for sufficiently small $\varepsilon > 0$.

PROOF:

The proof of Lemma 1 shows that $\mu_D(s; \delta, \phi) = \mu_F(s; \delta, \phi) = \mu_F(m; \delta, \phi) = 0$. Equations (11) imply

$$\begin{aligned} (16a) \quad \mu_D(s; \delta, \phi) &= (e^{-\delta(s)} + e^{-\delta(s)-\phi(s)})(s-c) - b \\ &= 0 \end{aligned}$$

$$\begin{aligned} (16b) \quad \mu_F(s; \delta, \phi) &= (ke^{-k\phi(s)} + e^{-\delta(s)-\phi(s)})(s-c) - b \\ &= 0 \end{aligned}$$

$$\begin{aligned} (16c) \quad \mu_F(m; \delta, \phi) &= (ke^{-k\phi(m)} + e^{-\delta(s)-\phi(m)})(m-c) - b \\ &= 0. \end{aligned}$$

Let $\hat{h} \equiv h/h(s)$. Then (15) implies

$$\begin{aligned} (17) \quad \partial W(\delta - \varepsilon \hat{h}, \phi) / \partial \varepsilon|_{\varepsilon=0} &= b - (s-c)e^{-\delta(s)} \\ &\quad - (m-c)e^{-\delta(s)-\phi(m)}. \end{aligned}$$

Substituting (16a) into (17) yields

$$\begin{aligned} (18) \quad \partial W(\delta - \varepsilon \hat{h}, \phi) / \partial \varepsilon|_{\varepsilon=0} &= (s-c)e^{-\delta(s)-\phi(s)} \\ &\quad - (m-c)e^{-\delta(s)-\phi(m)}. \end{aligned}$$

Equations (16b) and (16c) imply

$$(19) \quad s-c = (m-c) \frac{ke^{-k\phi(m)} + e^{-\delta(s)-\phi(m)}}{ke^{-k\phi(s)} + e^{-\delta(s)-\phi(s)}}.$$

Substituting (19) into (18) yields, after rou-

tine factorization,

$$\begin{aligned} \partial W(\delta - \varepsilon \hat{h}, \phi) / \partial \varepsilon|_{\varepsilon=0} &= \frac{k(m-c)e^{-\delta(s)-\phi(m)-k\phi(s)}}{ke^{-k\phi(s)} + e^{-\phi(s)-\delta(s)}} \\ &\quad \times [e^{(1-k)(\phi(m)-\phi(s))} - 1] > 0. \end{aligned}$$

That establishes the result.

The coincidence of excess advertising in the discount medium and underadvertising in the full-price medium is slightly paradoxical, because it has been emphasized repeatedly that (at the margin) low-price ads increase welfare more than high-price ads. That is true within any single advertising medium, but not across media.¹³ In the example, the marginal highest-priced ad increases welfare more than the marginal lowest-priced ad because the favorable effect of advertising in the full-price medium overwhelms the unfavorable effect of charging the full price.

It is important to emphasize that there is no *presumption* that firms advertise excessively in discount media. The above example only demonstrates the *possibility*. It is easy to construct examples in which excess advertising does not occur (e.g., the above model, with $k \geq 1$). Indeed, positive correlation of readerships is implausible for newspapers.

IV. Related Research

All of the models in this paper satisfy the fundamental competitive assumption that many small firms produce a homogeneous good. One way to relax that assumption is

¹³In this particular example, firms that charge prices $p \in [s, m]$ advertise exactly optimally, but this is an artifact of the discontinuous distribution of reservation values (cf. footnote 10). If the parameters of the example are perturbed slightly to smooth the distribution of reservation values, then the argument of Section III-A implies that all firms advertise too little in medium F, and it is still true that all firms that advertise in medium D advertise too much in medium D.

to introduce large firms. Stahl (1989) constructs a model similar to the present model, except that firms enjoy economies of scale in advertising. In a one-shot symmetric mixed-strategy equilibrium, all firms under-advertise. Another way to relax the competitive assumption is to introduce differentiated goods. Elsewhere (Stegeman, 1986) I construct a model that is similar to the simple model of Section I, except that the product space is a circle and each firm chooses its product as well as its price and quantity of advertising. Small consumers are distributed uniformly around the circle. After firms send advertising, each consumer responds to the best offer that he receives, taking into account price and linear transportation costs. It is shown that firms under-advertise in any symmetric equilibrium, except for a borderline case in which firms advertise exactly optimally. The robustness of these results is unclear. Grossman and Shapiro (1984) construct a model in which firms exploiting economies of scale in advertising distribute themselves around the circle, and they find excess advertising in some cases.¹⁴

A different way to generalize the model is to admit the possibility of consumer search. Butters (1977) describes a bilateral-search model in which consumers search after observing ads. Butters shows that the addition of consumer search causes firms to advertise too much. Elsewhere (Stegeman, 1986) I add a similar consumer search process to the model of Section I. In that case, consumer search may or may not cause excess advertising, but every firm does advertise too much if consumer search costs are sufficiently small. A partial explanation is that the firm advertising the highest price makes a substantial fraction of its sales to con-

sumers who would otherwise have purchased after search. All of those sales are captured from lower-priced firms, a negative externality similar to the undercutting externality.

V. Conclusion

The contention that firms advertise too much has provoked much inconclusive debate. The complexity of the issues precludes any simple resolution, but it is possible to obtain a better understanding of the circumstances that tend to lead to excess advertising. This paper contributes to such an understanding. The general setting is a competitive market (i.e., small agents, free entry, and a homogeneous good) in which the sole purpose of advertising is to convey price information. In this setting, it has been shown that firms buy less price advertising than is socially optimal. The result is quite robust with respect to the agents in the market and the advertising technology. If firms advertise in several media, however, then an example has shown that excess advertising can occur in media used exclusively to advertise discount prices.

The conclusion that competitive firms provide too little informative advertising complements the conclusion of Stigler and Becker (1977) and Nichols (1985) that competitive firms provide the optimal quantity of persuasive advertising. These results jointly establish a foundation for the welfare analysis of advertising in noncompetitive markets.

High and Declining Prices Signal Product Quality

By KYLE BAGWELL AND MICHAEL H. RIORDAN *

High and declining prices signal a high-quality product. High prices are the efficient means of signaling, because the consequent loss of sales volume is most damaging for lower-cost, lower-quality products. As time passes, and the number of informed consumers increases, the signaling distortion lessens, resulting in a declining price profile. The prediction of high and declining prices is robust across a variety of dynamic models and is consistent with recent empirical findings. (JEL 022, 026)

The marketing literature has produced various evidence on price-quality relationships. Numerous experimental studies show that consumers infer a higher quality from a higher price (Kent B. Monroe, 1973). This inference is consistent with the findings of several case studies. Such diverse products as fountain-pen ink and car wax (André Gabor and Clive Granger, 1965) and vodka, skis, and television sets (Robert D. Buzzell et al., 1972) have been successfully introduced at high prices to connote high quality. A variety of empirical data is also available. Analyses of *Consumer Reports* data yield positive price-quality rank-order correlations for many products, and particularly for consumer durables (Eitan Gerstner, 1985; Gerard J. Tellis and Birger Wernerfeld, 1987). Moreover, a recent longitudinal analysis of *Consumer Reports* data for consumer durables indicates declining trends in (a) real prices, (b) price differentials between competing brands, and (c) the rank-order correlation between price and

quality (David J. Curry and Peter C. Riesz, 1988).¹

These "stylized facts" are consistent with two important features of markets. First, firms signal high-quality new products with prices that are above full-information profit-maximizing prices. Second, over time, as information about the product diffuses, this price distortion lessens or vanishes entirely.

We demonstrate the logic and robustness of this argument in several equilibrium models of behavior by consumers and firms. The models have different assumptions about consumer information. However, all of the models possess intuitively plausible equilibria in which higher-quality products are introduced at higher prices that decline over time.

Our essential argument is outlined as follows. Consider a market in which a firm introduces a new product possessing some innovative feature of uncertain quality. Some consumers can ascertain the quality, while others cannot, but all understand that a higher-quality product is more costly to produce. The most efficient way for the firm to signal high quality is to charge a price too high to be profitable if the product were in fact of lower quality. This high-price strat-

¹Curry and Riesz collected all test-study evaluations with five or more brands reported in *Consumer Reports* over a 20-year period. They retained only those durable products whose characteristics remained stable during at least three separate publication time periods.

egy is potentially successful for two reasons. First, the consequent loss of sales volume is less damaging to a higher-cost product. Second, a lower-quality product would lose more sales from informed consumers by charging a high price. Understanding this, uninformed consumers rationally infer higher quality from the higher price.

However, as consumers gain experience with the product and information about its quality diffuses, the portion of uninformed consumers in the market declines. Consequently, it becomes even more costly for the firm to signal a higher quality falsely to the uninformed. The firm can efficiently signal a higher quality with a smaller price distortion. Thus, a high and declining price path identifies a high-quality product.

A positive correlation between price and quality follows, because higher-quality products are more costly to produce, so that signaling distorts upward the price of newly introduced high-quality products. As information diffuses, signaling distortions diminish, and the prices of newer products converge downward to those of older products of corresponding quality. An associated weakening of the correlation between price and quality can then be explained by measurement errors in the data. Thus, the theory appears to be consistent with the stylized facts.

Our conclusion that high-quality products have a downward sloping price profile differs from that of previous theoretical contributions to the economics literature. For example, Carl Shapiro (1983) shows that a monopolist charges a high and declining price if consumers optimistically overestimate product quality and charges a low introductory price if consumers pessimistically underestimate product quality. However, these conclusions depend on an assumption that consumers have adaptive expectations about product quality with no possibility of price signaling.

Paul Milgrom and John Roberts (1986) focus on the introductory phase of a non-durable product's life and argue that prices will rise over time as repeat buyers learn about their own preferences. Their analysis is similar to ours in that they also recognize

the potential for high prices to signal high (expected) quality due to cost effects. However, we abstract from short-run experimental-buying effects and focus on the long-run trends associated with the signaling of product quality.²

In a dynamic model of consumer learning, Kenneth L. Judd and Riordan (1987) show that high-quality prices tend to rise after the introductory period. This is because signaling does not occur until after consumers have gained experience with the product, which follows from an assumption of cost parity for different-quality products. Moreover, they conjecture that, for multi-period extensions, price would eventually decline as consumers gain further experience.

John Conlisk et al. (1984) and Nancy L. Stokey (1981) have argued for a declining price path for a durable good of known quality. This path represents the firm's attempt to "skim" the market of higher-valuation buyers. Edward P. Lazear (1986) also predicts a declining price path, under the assumptions that the firm is unsure of the size of its demand and that consumers know quality. While these theories are complementary to ours, they do not provide direct insight into the relationships between price and quality described above.

Our distinction between informed and uninformed consumers is reminiscent of a related literature on product selection in which some consumers observe quality while others do not. In this context, Yuk-Shee Chan and Hayne Leland (1982), Russell Cooper and Thomas W. Ross (1984, 1985), Scott Davis (1989), Joseph Farrell (1980), Riordan (1986), and Asher Wolinsky (1983) argue that the presence of informed consumers enables high prices to signal high-

²This focus seems justified given the nature of the long-run data we seek to understand (see footnote 1). Further, introductory offers to inspire repeat purchases are less relevant for consumer durables than for non-durables, because of the infrequency of consumer purchases of durable goods. For other models of introductory offers and repeat purchases that focus on different issues, see Bagwell (1987), Jacques Crémer (1984), and Joseph Farrell (1986).

quality choices. While our work is related, we take quality to be exogenous and also analyze the role of production costs in establishing high prices as signals. Indeed, we find that high prices can signal high quality even if all consumers are uninformed. Informed consumers are not necessary for the signaling of a given quality, but they do determine the size of the signaling distortion.

Finally, we note independent work by Garey Ramey (1986) and Doron Fertig (1988). They analyze a static model with a continuum of types and no informed consumers and demonstrate a unique separating equilibrium in which high prices signal quality. Our model has only two cost-quality types, introduces informed consumers, and uses the "intuitive criterion" (In-Koo Cho and David M. Kreps, 1987) to select among equilibria. Ramey and Fertig do not develop predictions about the time path of prices.³

The paper is organized in three sections. Our basic results are developed in a static context in Section I. Various multiperiod extensions are analyzed in Section II. Sections I and II may have methodological interest. The intuitive criterion is actively employed in each section, and the criterion is applied in Section II to dynamic signaling games with the possibility of multiple dimensions of private information. Our conclusions are summarized in Section III.

I. Basic Model

Consider a one-period consumer market in which a firm has introduced a new product with a novel feature of uncertain quality. For simplicity, assume that quality is either high or low: $q \in \{H, L\}$.

The production technology is common knowledge. The average cost of a high-quality product is constant and equal to $c > 0$,

while low-quality production cost is normalized to zero without loss of generality.

There are many potential consumers of the new product, approximated by a continuum of mass M (Judd, 1985), each with a potential demand for one unit. Consumers have a common reservation price, $P^L > 0$, for a low-quality product. On the other hand, consumers have heterogeneous reservation prices for a high-quality product, uniformly distributed between P^L and $(1 + P^L)$. The uniform distribution is convenient because it generates a linear demand for a high-quality product.

Some consumers are informed about product quality, while remaining consumers believe that quality is high with probability r . This prior belief is common knowledge. Let X denote the ratio of informed to uninformed consumers.

At the beginning of the period, the firm and informed consumers observe the true quality of the product. The firm then sets a price P , and uninformed consumers update their beliefs about product quality on the basis of this signal. Let $b = b(P)$ be the uninformed consumers' posterior belief that quality is high when the price is P . Consumers are assumed to make purchase decisions that maximize expected utility (i.e., the expected reservation price minus P), given beliefs. This process generates an informed demand curve, in which a fraction $1 + P^L - P$ of informed consumers buy when $P \in [P^L, 1 + P^L]$ and $q = H$, and an uninformed demand curve, characterized by a fraction $1 + (P^L - P)/b$ of uninformed consumers buying when $P \in [P^L, b + P^L]$ and quality is believed to be high with probability b . With these demand curves and our assumptions on cost technologies, the profit of a firm with quality q and price P facing uninformed consumers with belief b , denoted $\pi(q, b, P)$, is straightforward to define explicitly.⁴ We assume that the objective of the firm is to maximize profits.

³Also, Jean Tirole (1988 Ch. 2) has a nice expository discussion of price as a signal of quality which refers to an earlier working paper (Bagwell and Riordan, 1986), which this article supersedes.

⁴For example, if $P \in (P^L, b + P^L)$, then $\pi(L, b, P) = P[1 + (P^L - P)/b]M/(1 + X)$ and $\pi(H, b, P) = (P - c)[(1 + P^L - P)X + (1 + (P^L - P)/b)]M/(1 + X)$.

These actions and objectives define an extensive-form game of incomplete information with multiple sequential equilibria (Kreps and Robert Wilson, 1982). A sequential equilibrium requires that the firm and consumers act in a sequentially rational fashion and that uninformed consumers update beliefs using Bayes' rule on the equilibrium path. As usual, we distinguish between separating equilibria (in which high- and low-quality firms choose different prices) and pooling equilibria. However, we do restrict attention to pure-strategy equilibria.

We select plausible equilibria by imposing the "intuitive criterion" (Cho and Kreps, 1987). Consider an equilibrium in which the firm earns profits of $\pi(H)$ and $\pi(L)$ for high- and low-quality products, respectively. Then the equilibrium satisfies the intuitive criterion if there does not exist a price P' such that: (a) $\pi(H, 1, P') > \pi(H)$ and (b) $\pi(L, 1, P') < \pi(L)$. Intuitively, if such a price P' did exist, then uninformed consumers should believe that only a high-quality firm would charge P' , which by (a) causes the equilibrium to fail.⁵

Letting $P(q)$ denote the equilibrium price charged by a type- q firm, we now state our first two lemmas, which are almost obvious.

LEMMA 1: *In any equilibrium, $P(q) \geq P^L$ for $q \in \{H, L\}$.*

PROOF:

The function $\pi(q, b(P), P)$ is strictly increasing in P , for all $q \in \{H, L\}$ and all functions $b(\cdot)$, when $P < P^L$. Thus, were $P(q)$ less than P^L , the type- q firm could increase its price slightly and increase profits.

LEMMA 2: *In any separating equilibrium, $P(H) > P^L$ and $P(L) = P^L$.*

⁵We use the intuitive criterion throughout to restrict the class of equilibria. A weaker refinement is to eliminate dominated strategies (Elon Kohlberg and Jean-Francois Mertens, 1986; Milgrom and Roberts, 1986). This refinement is sufficient for all of our results for separating equilibria and for some of our work on pooling equilibria. The intuitive criterion is necessary, however, for Theorems 3 and 6.

PROOF:

A low-quality firm earns zero profits in a separating equilibrium if $P(L) > P^L$ and positive profits if $P(L) = P^L$. Therefore, the results follows from Lemma 1.

In a separating equilibrium, the low-quality firm charges P^L and the high-quality firm charges some higher price. Moreover, it must be that $\pi(L, 0, P^L) \geq \pi(L, 1, P(H))$; otherwise, the low-quality firm would mimic its high-quality counterpart. We are thus led to consider the set

$$\{P | \pi(L, 0, P^L) = \pi(L, 1, P)\}.$$

This equation has an upper and lower root,

$$\bar{P}(X) = [(1 + P^L)/2]$$

$$+ \left(\left[(1 + P^L)^2/4 \right] - P^L(1 + X) \right)^{1/2}$$

and

$$\underline{P}(X) = [(1 + P^L)/2]$$

$$- \left(\left[(1 + P^L)^2/4 \right] - P^L(1 + X) \right)^{1/2}$$

expressed as functions of X .

We assume that $1 > P^L$ and represent $\bar{P}(X)$ and $\underline{P}(X)$ by the upper and lower boundaries of the parabola in Figure 1.⁶ These equations have no solution for values of $X > \bar{X}$. For $X \leq \bar{X}$, any price inside the parabola, $P \in (\underline{P}(X), \bar{P}(X))$, satisfies $\pi(L, 0, P^L) < \pi(L, 1, P)$; the low-quality firm would mimic any such price. This leads immediately to the following lemma.

⁶If $P^L \geq 1$, then for $\varepsilon = P - P^L > 0$, $\pi(L, 1, P) = \pi(L, 0, P^L) - [P^L X + \varepsilon(P^L - 1) + \varepsilon^2]M/(1 + X) < \pi(L, 0, P^L)$, so that a low-quality firm's marginal revenue for a price increase above P^L is negative no matter how beliefs adjust. Thus, if $P^L \geq 1$, then mimicry is never profitable for the low-quality firm, and the problem degenerates. The following can be shown: if $P^L \geq 1 + c > 1$, then the unique equilibrium has $P(H) = P(L) = P^L$; while if $1 + c \geq P^L \geq 1$, then the unique equilibrium has $P(L) = P^L$ and $P(H) = (1 + P^L + c)/2 \equiv P^H$. $P^L < 1$ is thus the interesting case.

FIGURE 1. SEPARATING PRICES

LEMMA 3: *If $X < \bar{X}$, then in any separating equilibrium either $P(H) \geq \bar{P}(X)$ or $P(H) \leq \underline{P}(X)$.*

It is important to understand the parabola in Figure 1. By mimicking a high-quality price $P(H) > P^L$, the low-quality firm both gains and loses. It gains by tricking uninformed consumers with reservation prices at or above $P(H)$ into buying at a higher price, but it loses because all informed consumers and the remaining uninformed consumers refuse to buy at that price. The gains outweigh the losses for prices inside the parabola; for these prices, the low-quality firm finds mimicry profitable.

When all consumers are uninformed ($X = 0$), a price slightly above P^L is certainly worth mimicking, as only a very few consumers refuse to buy at the higher price. It follows that the lower branch of the parabola begins at P^L , reflecting the fact that all uninformed consumers buy at this price regardless of beliefs. As price climbs higher, eventually sales to uninformed consumers are sufficiently restricted that mimicry becomes unattractive. The critical price marking the beginning of the upper branch of the parabola is easily shown to be 1. When the ratio of informed to uninformed consumers (X) rises, it becomes increasingly costly for the low-quality firm to mimic its

high-quality counterpart and thereby sacrifice all informed purchases. For this reason, the parabola narrows about $(1 + P^L)/2$, the maximizer of $\pi(L, 1, P)$. This is the low-quality firm's monopoly price when all uninformed consumers believe it to be high-quality. For X above \bar{X} , the low-quality firm refuses to mimic even $(1 + P^L)/2$.

The high-quality firm's full-information monopoly price is $P^H \equiv (1 + P^L + c)/2$, the maximizer of $\pi(H, 1, P)$. However, with uninformed consumers, the high-quality price may be distorted upward as shown in the following theorem. The theorem establishes necessary conditions for a separating equilibrium satisfying the intuitive criterion.

THEOREM 1: $P(H) = \max\{\bar{P}(X), P^H\}$ and $P(L) = P^L$ are the only separating equilibrium prices satisfying the intuitive criterion.

PROOF:

Lemma 2 implies $P(L) = P^L$, so suppose $P(H) \neq \max\{\bar{P}(X), P^H\}$ and consider Figure 2. X^H satisfies $\bar{P}(X^H) = P^H$. For $X > X^H$, the intuitive criterion fails by setting $P' = P^H$. For $X \leq X^H$, Lemma 3 rules out $P(H) \in (\underline{P}(X), \bar{P}(X))$. Moreover, the intuitive criterion fails for $P' \in (\bar{P}(X), P(H))$ if $P(H) > \bar{P}(X)$, and for $P' \in (P(H), \underline{P}(X))$ if $P(H) < \underline{P}(X)$. This leaves the possibility that $P(H) = \underline{P}(X)$, but it is straightforward to show that $c > 0$ implies $\pi(H, 1, \bar{P}(X)) > \pi(H, 1, \underline{P}(X))$, from which it follows that $P' = \bar{P}(X) + \varepsilon$ violates the intuitive criterion for sufficiently small ε .

Theorem 1 identifies two cases. If $P^H \geq \bar{P}(X)$, then the separating equilibrium has $P(H) = P^H$ and $P(L) = P^L$. This is because the low-quality firm is unwilling to mimic the high-quality firm's favorite price. The more interesting case emerges when $P^H < 1$, or equivalently $P^L + c < 1$, and separation is potentially costly for the high-quality firm. In this case, a supramonopoly price is charged if the ratio of informed to uninformed consumers is small.

COROLLARY 1: *If $P^H < 1$ and X is sufficiently small, $P(H) = \bar{P}(X) > P^H$ and $P(L) = P^L$ are the only separating equilibrium prices satisfying the intuitive criterion.*

FIGURE 2. EQUILIBRIUM SEPARATING PRICES

For expositional reasons, we assume henceforth that $P^H < 1$.

Figure 2 illustrates the prices charged in a separating equilibrium satisfying the intuitive criterion (the parabola is the same as in Fig. 1). It may seem surprising that a high-quality firm separates with $\bar{P}(X)$ instead of a lower price $\underline{P}(X)$, when X is small. However, a simple intuition underlies this result. Because high-quality production is costly ($c > 0$), the full-information monopoly price P^H is closer to $\bar{P}(X)$ than to $\underline{P}(X)$.⁷ Put differently, the high price is the efficient means of separation because the forgone profit from a lost customer is less for the high-quality firm (Milgrom and Roberts, 1986). Thus, the high-quality firm prefers to separate with the high price.

⁷The assumption that higher-quality firms have at least somewhat higher costs of production is crucial. As the cost asymmetry between qualities diminishes, the high-quality firm's preferred separating price, $\bar{P}(X)$, remains constant; that is, $\bar{P}(X)$ is independent of c . In the limiting case when $c = 0$, prices corresponding to the lower branch of the parabola also satisfy the intuitive criterion. This is because the high-quality firm is then indifferent between $\bar{P}(X)$ and $\underline{P}(X)$. We believe $c > 0$ to be a realistic case.

So far we have characterized necessary conditions for a separating equilibrium. We now turn to existence.

Separation can occur only if the high-quality firm chooses not to monopolize informed consumers at the expense of losing uninformed consumers. Such a deviation is potentially attractive only if separation is costly for the high-quality firm, that is, when $X < X^H$ (see Fig. 2) in which case $P(H) = \bar{P}(X) > P^H$. Prices that might then increase high-quality profit must be inside the parabola and thus must also be prices that could increase low-quality profit. The intuitive criterion does not restrict beliefs for such prices, and at worst a deviation in this range could induce the belief of certain low quality. The high-quality firm will thus charge the price $P(H) = \bar{P}(X)$ when $X < X^H$ in a separating equilibrium if and only if $\pi(H, 1, \bar{P}(X)) \geq \pi(H, 0, P^H)$.⁸ Setting $\pi(H, 1, P) = \pi(H, 0, P^H)$ when $X < X^H$ de-

⁸ P^H is clearly the best price above P^L for the high-quality firm to deviate to when uninformed consumers believe quality is low. The high-quality firm will never deviate from $\bar{P}(X)$ to P^L (or lower), since $\pi(H, 1, \bar{P}(X)) \geq \pi(H, 1, \bar{P}(0)) > \pi(H, 1, P(0)) = \pi(H, 1, P^L)$.

FIGURE 3. NO-DEFECT PRICES

finds a "no-defect" root,

$$P^+(X) = P^H + [(1 + P^L - c)(1 + X)^{-1/2}/2]$$

which begins at $(1 + P^L)$ for $X=0$ and asymptotically declines to P^H , as shown in Figure 3. The high-quality firm has no incentive to defect if and only if $P(H) \leq P^+(X)$. Since "intuitive" beliefs can entail $b(P')=0$ for all $P' \in (P(X), \bar{P}(X))$, it is easily established that the low-quality firm is also unwilling to defect from the proposed separating equilibrium. We thus have the following existence theorem.

THEOREM 2: *A separating equilibrium satisfying the intuitive criterion exists if and only if $X \geq \bar{X}$ or if $X < \bar{X}$ and*

$$\Delta(X) \equiv P^+(X) - \bar{P}(X) \geq 0.$$

Two observations are in order, which we state below as corollaries. First, a separating equilibrium always exists if the ratio of informed to uninformed consumers is small because $\Delta(0) \equiv P^L > 0$. Second, it can be shown numerically that a separating equilibrium exists for any value of X unless P^L and c are small; Figure 4 illustrates parameter values for which separating equilibria fail to exist for some intermediate X .

COROLLARY 2: *A separating equilibrium satisfying the intuitive criterion exists if X is sufficiently small.*

COROLLARY 3: *A separating equilibrium satisfying the intuitive criterion exists if P^L or c is sufficiently large.*

We next turn to pooling equilibria. The following theorem establishes that, if the percentage of informed consumers is sufficiently small, then the only equilibrium satisfying the intuitive criterion is a separating equilibrium. In other words, when the market is very uninformed, there always exists a high price at which the high-quality firm can profitably distinguish itself.

THEOREM 3: *If X is sufficiently small, then no pooling equilibrium satisfies the intuitive criterion.*

PROOF:

We prove the result for $X=0$; the result follows for X close to 0 by continuity. Let $Q(P, b) \equiv [1 - (P - P^L)/b]M$ denote the quantity of sales at a price P when consumers believe high quality with probability b . In a pooling equilibrium, $P(H) = P(L) = P^*$, and $b(P^*) = r$. The high- and low-quality firms earn profits $\pi(H) \equiv (P^* - c)Q(P^*, r)$ and $\pi(L) \equiv P^*Q(P^*, r)$, respectively. Clearly $1 + r > P^* \geq \max\{P^L, c\}$; otherwise, one or the other type of firm would defect. Thus, $\pi(L) > \pi(H) \geq 0$. Since $P^*Q(P^*, 1) > \pi(L)$, there exists $P'' > P^*$ such that $\pi(L, 1, P'') \equiv P''Q(P'', 1) = \pi(L)$ and $\pi(H, 1, P'') = \pi(H) + c[Q(P^*, r) - Q(P'', 1)] > \pi(H)$. Moreover, $PQ(P, 1)$ is decreasing in P at P'' . Therefore, $P' \equiv P'' + \varepsilon$ violates the intuitive criterion for $\varepsilon > 0$ sufficiently small.

Pooling is therefore impossible if X is sufficiently small. Similarly, if the market is sufficiently well informed that X is large, then pooling is impossible to maintain, as each firm type prefers to deviate and monopolize informed consumers. For example, if $X \geq \bar{X}$ (see Fig. 1), then pooling is clearly impossible, because the low-quality firm would not select $P > P^L$ even if it were

FIGURE 4. PARAMETER VALUES SUPPORTING SEPARATION: FOR $\{P^L, C\}$ SUCH THAT $P^L > P^L(C)$, A UNIQUE SEPARATING EQUILIBRIUM SATISFYING THE INTUITIVE CRITERION EXISTS; IF INSTEAD $P^L < P^L(C)$, A SEPARATING EQUILIBRIUM MAY FAIL TO EXIST FOR INTERMEDIATE VALUES OF X

then believed to certainly have a high-quality product. The critical X beyond which pooling is impossible is actually smaller than \bar{X} , since pooling only generates the belief $b(P(L)) = r$. This point is stated in the following theorem, as is the related point that pooling is impossible when consumers' prior belief of high quality is pessimistic and, correspondingly, the profits from pooling are low.⁹

THEOREM 4: *If $r \leq \max\{P^L, c - P^L\}$ or $X \geq (r - P^L)^2 / 4rP^L$, then no pooling equilibrium exists satisfying the intuitive criterion.*

⁹By Theorems 2, 3, and 4 and Corollary 2, pure-strategy sequential equilibria satisfying the intuitive criterion might not exist if r is small and X is in an intermediate range. However, equilibria do exist satisfying the intuitive criterion in which the high-quality firm selects a price $P(H) > P^L$, the low-quality firm mixes between $P(H)$ and P^L with weights λ and $1 - \lambda$, and uninformed consumers believe high quality with probability b , where $P(H)$, λ , and b satisfy $b = r/[r + (1 - r)\lambda]$, $\pi(H, b, P(H)) = \pi(H, 0, P^H)$, and $\pi(L, b, P(H)) = \pi(L, 0, P^L)$.

PROOF:

By Lemma 1, pooling can never occur at $P < P^L$. Moreover, since $1 > P^L$, pooling at $P = P^L$ violates the intuitive criterion as the high-quality firm would deviate to $\bar{P}(X)$. A necessary condition for pooling at P is $\pi(L, r, P) \geq \pi(L, 0, P^L)$. Suppose pooling occurs at $P > P^L \geq r$. Let $M/(1 + X)$ denote the stock of uninformed consumers and let $\varepsilon \equiv P - P^L > 0$. Then $\pi(L, r, P) = \pi(L, 0, P^L) - [\varepsilon(P^L - r)/r + \varepsilon^2/r]M/(1 + X) < \pi(L, 0, P^L)$, a contradiction. Suppose next that pooling occurs when $r \leq c - P^L$. Pooling at P requires $P \geq c$ and $P < r + P^L$ (lest the low-quality firm deviate to P^L), which is contradictory. Finally, suppose $r > \max\{P^L, c - P^L\}$. Then it is easy to show that $X \geq (r - P^L)^2 / 4rP^L$ implies that at $P > P^L$, $\pi(L, r, P) \leq \pi(L, r, (r + P^L)/2) < \pi(L, 0, P^L)$, a contradiction.

Finally, if r is big and X is intermediate, pooling equilibria satisfying the intuitive criterion may exist. The possible prices for such equilibria are easily restricted. First, pooling at or below P^L is inconsistent with the intuitive criterion, as argued in the proof

FIGURE 5. THE POOLING PARABOLA

of Theorem 4. Second, given that pooling must occur above P^L , the pooling price must certainly be inside the parabola, or the low-quality firm would deviate to P^L . In fact, since pooling only gives the belief $b(P(L)) = r$, a tighter bound can be found. Setting $\pi(L, r, P) = \pi(L, 0, P^L)$ gives the prices at which the low-quality firm is just willing to pool. The corresponding roots are

$$\bar{P}_r(X) = [(r + P^L)/2]$$

$$+ \left(\left[(r + P^L)^2/4 \right] - rP^L(1 + X) \right)^{1/2}$$

$$\underline{P}_r(X) = [(r + P^L)/2]$$

$$- \left(\left[(r + P^L)^2/4 \right] - rP^L(1 + X) \right)^{1/2}$$

As shown in Figure 5, a "pooling parabola" inside the initial (separating) parabola is thus defined. The pooling parabola is drawn under the assumption that $r > P^L$ and is not defined for $X \geq (r - P^L)^2/4rP^L$, as suggested by Theorem 4. Any price outside of the pooling parabola has $\pi(L, r, P) < \pi(L, 0, P^L)$ and therefore cannot be supported as a pooling equilibrium. We thus have the following necessary condition for pooling.

THEOREM 5: *In any pooling equilibrium satisfying the intuitive criterion, $\underline{P}_r(X) \leq P(H) = P(L) \leq \bar{P}_r(X)$.*

Therefore, if an intuitive pooling equilibrium does exist, then r must be large, X must be intermediate, and the pooling price must be lower than the intuitive separating price for high quality.

II. Multiperiod Extensions

A. Interpreting the Static Results

We begin by offering a multiperiod interpretation of the static results of the previous section. Suppose that the market evolves in two periods. In the introductory period, the market is poorly informed about the characteristics of the product; the ratio of informed to uninformed consumers (X_1) is close to zero. Over time, information about the product diffuses through published quality reviews (e.g., *Consumer Reports*). Thus, during the mature phase of the market, the ratio of informed to uninformed consumers (X_2) is larger.

A high-quality product ($q = H$) will be introduced at a price that is distorted above the full-information monopoly price (Corollary 1 and Theorem 3). As information diffuses, it becomes easier to signal high quality, and the size of this distortion is reduced. If X_2 is sufficiently large, then a lower price signals high quality during the mature period (Theorem 4). For intermediate values of X_2 , pooling might occur during the mature phase; however, even a pooling price must be below the introductory price (Theorem 5). Therefore, high-quality products exhibit high and declining prices in either case.

A low-quality product, on the other hand, is introduced and remains at a low price P^L if X_1 is small and X_2 is large (Theorems 1, 3, and 4). If, instead, X_1 is small and X_2 is in an intermediate range, then the product is introduced at a low price but might rise to a higher pooling price in the mature phase (Theorems 1 and 5). However, this possibility is unlikely to be observed, because pooling can occur only if the prior probability of low quality is small (Theorem 4). Therefore, we conclude that, on average, prices will tend to fall as the market evolves.

In summary, our results appear to be consistent with the stylized facts for consumer durables (see the Introduction). Consider a reasonably well-defined product category, such as microwave ovens or color TVs. Over time, quality improvements lead

to the introduction of new products, but information about the value of these improvements diffuses gradually. New, higher-quality products are introduced at higher prices, resulting in a positive rank-order correlation between price and quality. As consumers gain information about new products, prices on average decline over time, since it becomes easier or unnecessary to signal quality, and price differentials narrow.

Finally, a weakened correlation between price and quality might be explained by measurement errors in the data. To understand this point, suppose that price and quality were perfectly rank-order correlated but that price differentials narrowed over time. Suppose further that prices and quality were measured with error and that this measurement error was independently and identically distributed over time. Then the measured rank-order correlation between price and quality would tend to decline.

This interpretation of our static results can be formalized in a two-period extensive-form game under the following assumptions. First, the populations of consumers in each of the two periods are distinct. That is, a consumer enters the market at the beginning of one or the other period, either makes a purchase or does not, and then leaves the market at the end of that period. In other words, we are taking a long-run view of the evolution of the market.

Second, upon entering the market, consumers only observe the current price. Specifically, consumers in the mature phase do not know what price was charged by the firm in the introductory phase. They do, however, know the date, that is, whether they are in the introductory or mature phase. (We relax these assumptions below.) As new consumers are ignorant of past prices, we refer to this model as the *ignorant-consumer model*.

Finally, information diffusion is independent of market activity. During the introductory phase, most consumers cannot distinguish a high-quality product prior to consumption, although some small fraction might be able to do so, say through inspec-

tion, because of some related expertise. During the mature phase, a new population has better information about product quality, because of the availability of published quality reviews. However, the ratio of informed to uninformed consumers in the mature period is independent of the quantity of sales in the first period.

Under these assumptions, the multi-period model decomposes into a sequence of one-period models, with our results of the previous section applying to each period. The fundamental dynamic variable is the ratio of informed to uninformed consumers, X_t , which by assumption increases over time (Bagwell and Riordan, 1986).

The assumption that information diffusion is independent of market activity might be important for our basic conclusion that high and declining prices signal product quality. Suppose instead that the number of informed consumers during the mature phase depends on the number of introductory sales. This might be the case if word-of-mouth communication about personal experience were an important mechanism for information diffusion. In this case, high prices which discourage sales become a less attractive method of signaling high quality. The high-quality firm might instead prefer to signal with a low price, in which case price would tend to rise over time.

However, word-of-mouth communication is not a particularly good method of information diffusion for many products. For example, for many durable products (e.g., smoke alarms), it is difficult to determine quality even after purchase. For such products, quality reviews or the advice of experts are much more important sources of information diffusion.

Further, word-of-mouth communication may be a very noisy source of information if there is an idiosyncratic component to consumer tastes. For example, knowing that my neighbor likes his new microwave oven may not be a very good indicator that I will like it. On the other hand, knowing that 90 percent of consumers like it is much more informative. Published quality reviews, such as those in *Consumer Reports*, accomplish this information aggregation. Our model

could be extended to introduce an idiosyncratic taste component (Milgrom and Roberts, 1986).¹⁰

We conclude that our independence assumption is consistent with a long-run view of markets, in which the primary source of information diffusion is published quality reviews. This seems particularly pertinent for explaining stylized facts based on data published in *Consumer Reports*. It is plausible that the availability of published quality reviews is independent of first-period pricing.

We turn now to a relaxation of some other assumptions about consumer information.

B. Confused Consumers

In the above-described ignorant-consumer model, the ratio of informed to uninformed consumers is common knowledge. In our model, this is equivalent to assuming that each consumer knows the age of the firm, since by assumption X_t increases strictly over time. This is clearly an extreme assumption, as it seems reasonable that consumers might also be incompletely informed about the demand side of the market. We address this issue in a very simple way by assuming that consumers in any period observe only the current price and not the age of the firm. We continue to assume that some fraction of consumers are informed about quality in each period. As consumers are confused about the date, we refer to this model as the *confused-consumer model*.

An important novelty of the confused-consumer model is that the firm now has two dimensions of private information: the

¹⁰The assumption that initial sales volume influences the future information state is in fact problematic, even if quality is nonidiosyncratic and easily evaluated after experience. In particular, in a separating equilibrium, each current consumer believes he knows quality whether or not he chooses to buy. Word-of-mouth communication then affects the rate of diffusion only if a consumer who knows quality communicates more effectively than does a consumer who believes himself to know quality.

quality of its product and the prevailing ratio of informed to uninformed consumers. Consequently, the price set by the firm potentially signals information about both. Uninformed consumers will thus attempt to update their beliefs about both unknown variables.

Formally, we model this situation as a two-period extensive-form game with the following structure. At any period t , the ratio of informed to uninformed consumers is actually X_t . The firm knows this ratio as well as the quality of its product and chooses a price, $P_t(q)$. Uninformed consumers at any date do not observe quality and also do not know whether they are in period one or two. That is, an uninformed consumer knows that $q \in \{H, L\}$ and $X \in \{X_1, X_2\}$, where H , L , X_1 and X_2 are all commonly known values and $X_2 > X_1$, but he does not know the actual realizations of q and X . Upon observing a price P , an uninformed consumer forms a (stationary) belief $b(P)$, representing the likelihood of high quality. In a sequential equilibrium, the belief of uninformed consumers must agree with Bayes' rule for prices that could occur (for some quality and date) in equilibrium.¹¹

The intuitive criterion can be usefully employed in this environment. A sequential equilibrium fails the intuitive criterion if there exists an out-of-equilibrium price P' such that (a) $\pi_t(H, 1, P') > \pi_t(H)$ for some t and (b) $\pi_t(L, 1, P') < \pi_t(L)$ for all t , where $\pi_t(q)$ are equilibrium profits at date t for quality q , with $t \in \{1, 2\}$ and $q \in \{H, L\}$. Intuitively, if there exists an out-of-equilibrium price that is profitable for a high-quality firm at some date when uninformed

consumers believe it to be high-quality, but which is never profitable for a low-quality firm no matter what uninformed consumers believe, then uninformed consumers must believe that there is high quality at that price. In effect, the firm makes an implicit speech as to quality and date with the selection of the price P' .

We will continue to interpret the first period as an introductory phase in which X_1 is close to zero and the second period as a mature phase with X_2 large. Our main result is that the high-quality firm will separate with a high price in period one, and the prices of both types of firm will decline. This equilibrium exhibits intertemporal pooling, in that the young, low-quality firm mimics the price of the mature, high-quality firm.¹² Thus, the general implications of the ignorant-consumer model also are true in the confused-consumer model.

THEOREM 6: *In the confused-consumer model, if X_1 is sufficiently small, then in any equilibrium satisfying the intuitive criterion, $P_1(H) \geq P_2(H)$, $P_1(H) \in (P^H, \bar{P}(X_1)]$, $b(P_1(H)) = 1$, and $P_1(L) \geq P_2(L)$. If in addition X_2 is sufficiently large, then $P_1(H) > P_2(H)$ and $P_1(L) = P_2(H) > P_2(L) = P^L$.*

The theorem has a simple intuition. (A formal proof is in the Appendix.) The declining path of prices follows from the assumption that the number of informed consumers increases through time. As the market becomes more informed, distortions away from complete-information monopoly prices become more costly. Thus, a rising price profile is not an optimal strategy for a firm, since it entails greater distortions when the market is more informed. The firm would be better off, for example, to reverse the order of its two prices. The assumption that the number of informed consumers is initially small is not important in ruling out rising price profiles but does ensure that the introductory high-quality price separates; the logic is similar to that for Theorem 3.

¹¹The specific nature of the consumer arrival process will determine the consumers' priors over dates. It is perhaps easiest to imagine that the process treats consumers anonymously, pulling out a certain fraction in period one and the remainder in period two, in which case consumers have common priors over dates (Bagwell and Riordan, 1986). The consumers' priors over dates will affect beliefs as to quality only for prices that would be charged at different dates by the high- and low-quality firms. In any event, Theorem 6 below characterizes the necessary characteristics of equilibrium and is independent of the details of the arrival process.

¹²Bagwell and Riordan (1986) give an example of an equilibrium with these characteristics.

It is interesting to note that the initial high-quality price in the confused-consumer model is never higher and, indeed, may be lower than the corresponding price in the ignorant-consumer model when X_1 is small. Since the introductory period is when the low-quality firm has the greatest incentive to mimic, the price $\bar{P}(X_1)$ is sufficient to separate even when consumers are confused as to the date. Furthermore, an introductory price strictly below $\bar{P}(X_1)$ may separate when consumers are confused, because the low-quality firm initially earns a larger profit by mimicking the mature, high-quality price than by charging P^L .

C. Hindsightful Consumers

We close this section by briefly considering another assumption, that consumers observe both the age of the firm and the entire history of prices; we call this model the *hindsightful-consumer model*. This is a strong assumption (e.g., past prices are not typically reported in *Consumer Reports*).

In this model, uninformed consumers in period one observe a first-period price P_1 and attempt to infer quality, while uninformed consumers in period two base their beliefs on a pair of prices, P_1 and P_2 . Sequential equilibrium then requires that the beliefs of an uninformed consumer be consistent with Bayes' rule for any price or pair of prices that could occur in equilibrium. The sequential equilibria of the ignorant-consumer model are also equilibria of this model but have the property that consumers always ignore past prices in forming beliefs about product quality. However, there also exist other equilibria in which period-two consumers base their quality beliefs at least partially on period-one price.

Cho (1987) has generalized the intuitive criterion to multiperiod settings such as this. However, as Cho (1987 p. 1385) notes, this refinement is often very weak, and this is true in our model as well.¹³ Nevertheless,

there do exist plausible sequential equilibria—other than those of the ignorant consumer model—that are consistent with the stylized conclusion that high and declining prices signal quality.¹⁴

A particularly focal equilibrium is that which is the Pareto dominant separating equilibrium for the firm. To find this equilibrium, we solve

$$\max_{(P_1, P_2)} [\pi_1(H, 1, P_1) + \delta \pi_2(H, 1, P_2)]$$

subject to

$$\pi_1(L, 1, P_1) \leq \pi_1(L, 0, P^L)$$

and

$$\begin{aligned} \pi_1(L, 1, P_1) + \delta \pi_1(L, 1, P_2) \\ \leq \pi_1(L, 0, P^L) + \delta \pi_2(L, 0, P^L) \end{aligned}$$

where δ is a common discount factor. Our fundamental result is that the Pareto dominant separating equilibrium is characterized by high and declining high-quality prices, while low-quality prices are constant at P^L . The price dynamics for the hindsightful-consumer model are again qualitatively the same as for the ignorant-consumer model. In each case, the high-quality price begins high and then declines as the number of informed consumers increases and signaling becomes easier.

THEOREM 7: *In the hindsightful-consumer model, the Pareto dominant separating equilibrium is characterized by $P_1(H) \geq \bar{P}(X_1)$, $P_2(H) = P^H$ if $X_2 \geq X^H$, $P_2(H) \in [\bar{P}^H, \bar{P}(X_2)]$ if $X_2 < X^H$, and $P_1(L) = P_2(L) = P^L$.*

consumers. It follows that, using the intuitive criterion, period-one consumers are generally unable to associate a deviation with the high-quality product.

¹⁴For a more thorough discussion of the types of plausible separating equilibria in the hindsightful-consumer model, see Bagwell and Riordan (1989).

¹³The problem is that almost any deviant first-period price could improve profits for the low-quality firm, if the deviation were favorably interpreted by period-two

The proof of Theorem 7 is straightforward (Bagwell and Riordan, 1989).

It is interesting to compare the Pareto dominant separating equilibrium for the hindsight-consumer model with the separating path in the ignorant-consumer model. Numerical calculations reveal that the two paths agree if P^L is large. However, if P^L is small and X_2 is not too large, the hindsight-consumer model's equilibrium has $P_1(H) > \bar{P}(X_1)$ and $P_2(H) < \bar{P}(X_2)$. Here, the high-quality firm "front loads" the signaling process by signaling strongly in the introductory phase and then profit-taking in the mature phase.¹⁵

A general theme seems to arise from a comparison of the ignorant-, confused-, and hindsight-consumer models. In the focal separating equilibria of these models, the initial high-quality price is at least as high in the hindsight- as in the ignorant-consumer model, and is at least as high in the ignorant- as in the confused-consumer model. In effect, the more information consumers have about the initial period, the more difficult and the more important it is for the high-quality firm to signal strongly in that period. Since signaling involves high prices, the initial high-quality price is highest when consumers have hindsight and lowest when they are confused.

III. Conclusions

A high-quality good will be introduced at a high price that is lowered over time toward the full-information monopoly price. The high introductory price signals high quality, because a high-cost firm is more

willing to restrict sales volume than is a low-cost firm. Furthermore, a low-quality firm loses greater sales volume from a high price, since informed consumers refuse to buy at such a price. As information about product quality diffuses and more consumers become more informed, it therefore becomes easier for a high-quality firm to signal its quality. High-quality prices thus decline as the market matures.

Our prediction of high and declining prices is consistent with the stylized facts of the marketing literature.¹⁶ In particular, our model provides an explanation for the declining trends in consumer durables of real prices, price differentials between competing brands, and the rank-order correlation between price and quality.

The prediction is robust to a variety of assumptions about consumer information. Whether or not uninformed consumers know past prices and firm age, intuitively plausible equilibria exist in which high-quality products have high and declining prices.

Our model relies on many special features that can be relaxed. For example, linear demands and costs are not crucial for our conclusions.¹⁷ The two-period framework is also easily extended into a many-period setting.

Many interesting extensions do remain. It would be worthwhile to study an explicit model of word-of-mouth communication. Further empirical work might investigate how price-quality relationships depend on the amount and type of consumer information. One intriguing possibility is to interpret the publication of a *Consumer Reports* evaluation of a product group as a proxy for an increase in the "fraction of informed consumers." This suggests the empirical test that a *Consumer Reports* publication should itself lower the relative price of high-quality items and weaken price-quality correlation.

¹⁵More generally, since the ignorant-consumer equilibrium is not always the hindsight-consumer equilibrium, the high-quality firm has a clear incentive to ensure that past price information is available to uninformed consumers. By equipping consumers with hindsight, the high-quality firm may be able to generate a more profitable equilibrium. This point is reminiscent of work by B. Douglas Bernheim and Michael D. Whinston (1990), who argue that firms may seek multi-market contact so as to pool incentive constraints. Analogously, we find that a high-quality firm may want consumers to observe its past pricing decisions so as to pool its "no-mimic" constraints through time.

¹⁶It should be noted, however, that at least some of our "stylized facts" are in fact controversial (Valerie A. Zeithaml, 1988).

¹⁷Bagwell (1990) establishes that high prices signal a high-quality product in a model that allows for a general demand function and product quality choice.

APPENDIX

PROOF OF THEOREM 6:

Observe first that $P_t(H) > P^L$ and $P_t(L) \geq P^L$. $P_t(q) < P^L$ is impossible in equilibrium, as $P_t(q) = P^L$ earns greater profit always. Also, $P_t(H) = P^L$ is inconsistent with the intuitive criterion, because $\pi_t(H, 1, \bar{P}(X_1)) - \pi_t(H, b(P^L), P^L) > 0$ and $\pi_t(L, 1, \bar{P}(X_1)) \leq \pi_t(L, b(P^L), P^L) \leq \pi_t(L)$.

Next, X_1 small implies $b(P_1(H)) = 1$. To see this, suppose $b(P_1(H)) < 1$. From the proof of Theorem 3, there exists $P'' > P_1(H)$ such that $\pi_t(L, 1, P'') = \pi_t(L, b(P_1(H)), P_1(H)) \leq \pi_t(L)$ and $\pi_1(H) = \pi_1(H, b(P_1(H)), P_1(H)) < \pi_1(H, 1, P'')$. $P' = P'' + \varepsilon$ with $\varepsilon > 0$ and small, then violates the intuitive criterion.

Given $b(P_1(H)) = 1$, $P_1(H) \in (P^H, \bar{P}(X_1)]$ follows. To see this, note that $P_1(H) = P^H$ induces $P_2(H) = P^H$ and thus $P_1(L) = P^H$, which contradicts $b(P_1(H)) = 1$. Further, $P_1(H) < P^H$ violates the intuitive criterion; for if $P_1(H) \in [(1 + P^L)/2, P^H]$, then $P' = P_1(H) + \varepsilon$, for $\varepsilon > 0$ and small, violates the intuitive criterion. On the other hand, if $P_1(H) < (1 + P^L)/2$, then as in the proof of Theorem 1, $P'' > P^H$ can be found for which $\pi_t(L, 1, P'') = \pi_t(L, 1, P_1(H)) \leq \pi_t(L)$ and $\pi_1(H, 1, P'') > \pi_1(H, 1, P_1(H)) = \pi_1(H)$. $P' = P'' + \varepsilon$ then violates the intuitive criterion. Finally, $P_1(H) > \bar{P}(X_1)$ is also inconsistent with the intuitive criterion, as can be seen by setting $P' = P_1(H) - \varepsilon$.

$P_1(H) \geq P_2(H)$ is straightforward to establish. Otherwise, since $b(P_1(H)) = 1$ and $P_1(H) > P^H$, $\pi_2(H) = \pi_2(H, b(P_2(H)), P_2(H)) < \pi_2(H, 1, P_1(H))$, and so the high-quality firm would do better to select $P_1(H)$ in period two as well.

Consider next $P_t(L)$. Clearly, $P_t(L) = P^L$ or $P_t(L) = P_2(H)$ at any t . $P_1(L) = P^L$ and $P_2(L) = P_2(H)$ is impossible, since

$$\begin{aligned} \pi_2(L, b(P_2(H)), P_2(H)) \\ \geq \pi_2(L, b(P^L), P^L) \end{aligned}$$

implies $\pi_1(L, b(P_2(H)), P_2(H)) > \pi_1(L, 0, P^L)$, contradicting $P_1(L) = P^L$. Hence, $P_1(L) \geq P_2(L) \geq P^L$.

We now impose the additional assumption that X_2 is sufficiently large, taken here to mean $X_2 > \bar{X}$ and $P^\dagger(X_2) < \bar{P}(X_1)$. $X_2 > \bar{X}$ implies $P_2(L) = P^L$, while $P^\dagger(X_2) < \bar{P}(X_1)$ can be shown to imply $P_2(H) \in (\underline{P}(X_1), \bar{P}(X_1))$. The latter result gives $P_1(L) = P_2(H)$. Since $b(P_1(H)) = 1$ and $P_2(H) > P^L$, we thus have $P_1(H) > P_2(H) = P_1(L) > P_2(L) = P^L$.

Striking for a Bargain Between Two Completely Informed Agents

By RAQUEL FERNANDEZ AND JACOB GLAZER*

This paper models the wage-contract negotiation procedure between a union and a firm as a sequential bargaining process in which the union must decide, in each period, whether or not to strike for the duration of that period. We show that there exist subgame-perfect equilibria in which the union engages in several periods of strikes prior to reaching a final agreement, although both parties are completely rational and fully informed. This has implications for other inefficient phenomena, such as tariff wars, debt negotiations, and wars in general. We characterize the set of equilibria, show that strikes can occur in real time, and discuss extensions of the model, such as lockouts and the possibility of multiple recontracting opportunities.

Economic theory has trouble explaining strikes.¹ As stated by Oliver Hart (1989 p. 25), "The difficulty is to understand why rational parties should resort to a wasteful mechanism as a way of distributing the gains from trade. Why could not both parties be made better off by moving to the final distribution of surplus immediately...and sharing the benefits from increased production?" A similar objection to developing a coherent theory of strikes is what John Kennan (1986 p. 1091) calls the "Hicks paradox," namely: "The main obstacle is that if one has a theory which predicts when a strike will occur and what the outcome will be, the parties can agree to this outcome in advance, and so avoid the costs of a strike. If they do this, the theory ceases to hold... If the parties are rational, it is difficult to see why they would fail to negotiate a Pareto optimal outcome."

This paradox has been resolved by resorting to informational imperfections, in par-

ticular, asymmetric information. Indeed, it is often thought that there are no other possible culprits for these inefficiencies.² David Card (1988 p. 1), for example, asserts that "It has long been recognized that any consistent theoretical model of strikes must appeal to some form of imperfect information." The basic idea underlying the asymmetric-information bargaining models developed in Anat Admati and Motty Perry (1987), Lawrence M. Ausubel and Raymond J. Deneckere (1989), Kalyan Chatterjee and Larry Samuelson (1987), Peter C. Cramton (1984), Drew Fudenberg et al. (1985), Sanford Grossman and Perry (1986), Hart (1989), Ariel Rubinstein (1985), and Joel Sobel and Ichiro Takahashi (1983) is that strikes, or delays in reaching agreement, are a signalling device. If a firm's profitability is unobservable by workers, then the willingness of a firm to delay agreement and therefore to forgo the output associated with such a delay serves as a signal of that firm's lower profits and allows a lower wage agreement to be reached. A high-profit firm would prefer to accept the higher wage agreement and obtain the revenue associated with pro-

¹For a review of theories that attempt to explain strikes, see John Kennan (1986).

²Although, of course, bounded rationality could produce inefficient behavior. See Orley Ashenfelter and G. E. Johnson (1969) for a bargaining model in which only one side behaves optimally.

duction in those periods. Empirical work by Henry S. Farber and Max H. Bazerman (1989) and by Card (1988), however, casts some doubt on the ability of this kind of theory to explain reality. Moreover, in most asymmetric-information models, the Coase conjecture holds. That is, as the length of time separating bargaining periods becomes arbitrarily small, so does the real time of delay (see Faruk Gul and Hugo Sonnenschein [1988] for a rigorous discussion of this result).

Behind the assertion that imperfect information is the sole force driving strikes lies the implicit belief that, in the absence of informational asymmetries, bargaining between two parties is efficient. Both the cooperative- and the noncooperative-bargaining literature can be seen as lending support to that belief. The solution concepts of cooperative-bargaining theory, such as the Nash bargaining solution, assume Pareto-efficient outcomes. Moreover, the best-known examples of Rubinstein's (1982) noncooperative-bargaining model also produce unique and Pareto-efficient equilibria. In the case of fixed bargaining costs of c_i per period (where i indexes the name of the player, and with no discounting), if $c_1 = c_2$ it is possible to have inefficient equilibria emerge; for any $c_1 \neq c_2$, however, the subgame-perfect equilibrium is efficient.

Our paper's contribution is to show that strikes and other wasteful phenomena, such as wars, can result as equilibrium behavior within a framework of perfect rationality and complete information. Irrationality or informational asymmetries, while undoubtedly important factors in the explanation of many inefficient activities, are not necessary conditions for these to occur. Bargaining between two perfectly informed agents need not be efficient.

We develop a modified version of Rubinstein's (1982) bargaining model.³ As in

Rubinstein's model, the two agents—in our case, a union and a firm—are assumed to bargain sequentially over discrete time and a potentially infinite horizon. The union and firm alternate in making offers of wage contracts, which the other party is free to accept or reject. In our model, however, there is also an old wage contract (this is what is being renegotiated). This matters because, upon either party's rejection of a proposed wage contract, the union faces another decision: whether or not to strike in that period. If the union chooses to strike, it forgoes the wage that it would have received by not striking and instead working that period. That wage is assumed to be the one stipulated by the old contract. Thus, a decision to strike is costly to both parties. The union does not get paid, and the firm does not receive the revenue net of the wage bill. There is no uncertainty in this model, and agents possess complete information.

We show that there exist multiple subgame-perfect equilibria, some of which are Pareto-inefficient. The latter equilibria can take the following form: along the equilibrium play, the union makes very high wage offers, which the firm rejects. The firm, in turn, makes very low wage offers, which the union rejects. In every period in which an offer is rejected, the union strikes. This behavior continues for T periods, after which time an offer that lies somewhere between the high and low wage offers is both made and accepted. Despite the fact that reaching that same final agreement T periods earlier would be a Pareto improvement, we show that neither party will attempt to deviate from the equilibrium play behavior described above. Any attempt by one of the parties to deviate and reach an earlier agreement results in both the firm and the union thereafter playing an efficient equilibrium, but one which adversely affects the deviating party. Thus, we are able to answer the question posed in the first paragraph as to why it is that rational (and completely

³After completion of this paper, it was called to our attention that Hans Haller (1988) and Steinar Holden (1989) have developed models very similar to ours. Haller (1988 p. 16) however, concludes that there are no inefficient equilibria and therefore no strikes in

equilibrium, since "With complete information and rational players, bargaining is efficient." We show this conclusion to be incorrect.

informed) agents may engage in inefficient behavior.

The primary purpose of this paper is not so much to propose an alternative theory of strikes as to dispel a popular misconception concerning the necessity of asymmetric information for an explanation of this phenomenon. While our model has the less attractive feature that strikes occur only in some of the equilibria, it is also true that strikes in our model are not an artifact of the discrete-time bargaining framework: strikes can occur in real time; that is, they can be lengthy despite agents' ability to negotiate extremely rapidly. Furthermore, our model (or an extension of it) has as an implication that the range of parameter values that support strikes is greater in boom periods than in periods of recession. This is suggestive of the empirical finding that strikes tend to be procyclical.⁴ Other testable implications of our model include the specification of a range (given by a function of the firm's revenue in the case of no strike and by the union's wage in the status quo contract) in which strikes should not be observed.

The paper is organized as follows. In Section I, we set up the model. We discuss the efficient equilibria in Section II and the inefficient ones in Section III. In Section IV, we analyze some extensions of the model: we allow the firm to engage in lock-outs, and we examine the effect of multiple (predetermined) recontracting opportunities. Our conclusions are presented in Section V.

I. The Model

We consider the following situation: two parties—a union (of L identical workers hereafter normalized to equal 1) and its firm—have a contract that specifies the wage that a worker in the union is entitled to per day of work. This contract, however, has come up for renegotiation. The institutional mechanism governing contract renegotia-

tions is assumed to be as follows: the union and firm alternate in making wage offers over discrete time periods $t \in \{1, 2, \dots\}$. In each odd-numbered period (a period is taken for simplicity to be a day) the union proposes a wage contract x_t . The firm then responds (R_t) by either accepting the offer (Y) or rejecting it (N). If the firm accepts the offer, negotiations are over, and the newly agreed upon wage contract is assumed to hold thereafter (we later relax this assumption and allow contracts to be renegotiated any number of times). If the firm rejects the wage offer, the union must then make a decision S_t : to strike (s) or not to strike (ns). If the union decides not to strike that period, workers work and receive the old wage w_0 , $0 \leq w_0 \leq F$, specified by the preexisting contract, and the firm obtains the revenue F associated with the union's output minus the wage bill, that is, $F - w_0$. If the union decides to strike, workers forfeit their wage that period, and the firm does not earn $F - w_0$. Each party's payoff in this period is normalized to zero. After the union executes its decision S_t , time advances one period. In every even-numbered period, the firm offers the union a wage contract y_t . The union then responds (Q_t) by accepting (Y) or rejecting (N) the firm's proposal. Once again, acceptance implies that this new contract holds thereafter. Rejection of the offer, on the other hand, faces the union with the strike decision. The same rules as described previously govern the consequences of the strike decision. Once the decision is executed, time advances one period. Note that this bargaining process can potentially last an infinite amount of time. Figure 1 depicts the first two periods of the game.

The firm possesses a discount factor of $0 < \delta_f < 1$, and the union possesses a discount factor of $0 < \delta_u < 1$. The union's objective is to maximize workers' utility, the discounted sum of wage earnings,

$$\sum_{t=1}^{\infty} \delta_u^{t-1} w_t$$

and the firm's objective is to maximize the

⁴See Kennan (1986) for a discussion of the empirical work in this area.

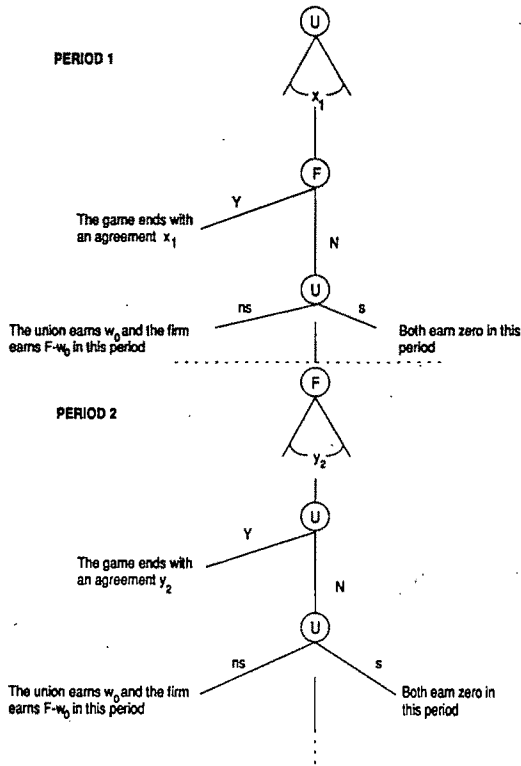

FIGURE 1. DIAGRAM OF THE FIRST TWO PERIODS OF THE GAME

discounted sum of profits,

$$\sum_{t=1}^{\infty} \delta_f^{t-1} (F - w_t).$$

Although the union is assumed to earn w_0 in the nonstrike periods prior to signing a new contract, it is also possible to view the negotiation process as including retroactive wage increases. This would not change any of our results, since what matters to the firm and to the union is the appropriately discounted value of earnings. Thus, a new wage contract w can be viewed as consisting partly of retroactive compensation and partly of wage increase.

We will be studying the subgame-perfect equilibria of the game described above. Subgame perfection is the natural refine-

ment of Nash equilibrium for a game with complete information, such as ours. Subgame perfection eliminates those equilibria based on "incredible" threats, that is, on threats that an agent would not be willing to carry out (they would be payoff-worsening for that player). That is, subgame-perfect-equilibrium strategies induce Nash equilibria in the game and in every proper subgame, including those subgames that will not be reached along the equilibrium play.

It is convenient to ask what the bargaining outcome would be if the union were committed to striking in every period in which it did not reach an agreement with the firm. As we will show, this is tantamount to assuming that the original wage contract does not exist, since w_0 is now no longer a possible cost of disagreement.

LEMMA 1: *If the union is committed to striking in every period in which there is a disagreement, then there is a unique subgame-perfect equilibrium to the bargaining game between the union and the firm. This equilibrium has agreement reached in the first period of negotiation and results in a wage contract of \bar{w} if bargaining commences in an odd-numbered period and has a contract of \bar{z} if bargaining commences in an even-numbered period, where*

$$\bar{w} = \frac{(1 - \delta_f) F}{1 - \delta_u \delta_f} \quad \bar{z} = \frac{\delta_u (1 - \delta_f) F}{1 - \delta_u \delta_f}.$$

PROOF:

See Rubinstein (1982) or Avner Shaked and John Sutton (1984).

Note that \bar{w} and \bar{z} are the solutions to Rubinstein's original bargaining game. The intuition underlying this result is that the union's commitment to strike in every period of disagreement transforms the game into Rubinstein's original bargaining model with both parties bargaining over a cake of size F . The fact that $\bar{w} > \bar{z}$ shows that the player who makes the first offer has an advantage in this kind of bargaining game.

II. Efficient Equilibria

In this section, we completely characterize the set of Pareto-efficient subgame-perfect equilibria. We first discuss three particular equilibria that are especially useful. One is the minimum wage contract that can be obtained in equilibrium, another is the maximum, and the third has the property that the union threatens to strike in each period in which an agreement is not reached.

LEMMA 2: *There is a subgame-perfect-equilibrium in which an agreement of w_0 is reached in the first period.*

PROOF:

The pair of subgame-perfect-equilibrium strategies given below generates a wage contract of w_0 in the first period. The union's strategy is never to strike (i.e., $S_t = \text{ns}$ for all t) and to offer $x_t = w_0$ in every odd-numbered t and, in every even-numbered t to reply to an offer y_t by

$$Q_t = \begin{cases} Y & \text{if } y_t \geq w_0 \\ N & \text{otherwise.} \end{cases}$$

The firm's strategy is to offer $y_t = w_0$ in every even-numbered t and, when t is odd, to reply to an offer x_t by

$$R_t = \begin{cases} Y & \text{if } x_t \leq w_0 \\ N & \text{otherwise.} \end{cases}$$

It is easy to check that these are subgame-perfect-equilibrium strategies.

Note that w_0 is the minimum wage contract that the union can receive, since it always has the option of working at the preexisting wage.⁵

⁵Furthermore, in a finite-horizon version of our model, w_0 is the sole subgame-perfect-equilibrium outcome; no strikes can occur. For a complete-information finite-horizon Rubinstein model (but with a commitment mechanism) capable of generating delays, see Chaim Fershtman and Daniel Seidmann (1990).

LEMMA 3: *If*

$$(1) \quad w_0 \leq \delta_u \bar{z}$$

there exists a subgame-perfect equilibrium in which an agreement of \bar{w} is reached in the first period.

PROOF:

A formal proof is contained in the proof of Theorem 2 below and is therefore omitted here.⁶

The following is an informal description of the strategies that generate the above equilibrium. The union offers the contract \bar{w} in every odd-numbered period, accepts any offer greater or equal to \bar{z} in every even-numbered period, and strikes in every odd-numbered period in which its request for \bar{w} is rejected and in every even-numbered period in which it is not offered at least \bar{z} . If, however, at some point, the union deviates from this rule, then the strategies call for both players to play thereafter according to the strategies described in Lemma 2. In other words, a deviation by the union is punished by having it accept the old wage contract of w_0 .

The maximum wage contract that the union can obtain, however, is not \bar{w} . This wage contract is established in the following lemma. Let

$$w' = \bar{w} + \delta_f w_0 (1 - \delta_u) (1 - \delta_u \delta_f)^{-1}$$

and

$$z' = \bar{z} + w_0 (1 - \delta_u) (1 - \delta_u \delta_f)^{-1}.$$

LEMMA 4: *If $w_0 \leq \delta_u z'$, there is a subgame-perfect equilibrium in which an agreement of w' is obtained in the first period. This is also the maximum wage contract that the*

⁶Theorem 2 provides a pair of strategies that produce \bar{w} as an outcome in some subgames. It is not difficult to see how they can be modified to generate \bar{w} as an agreement reached in the first period.

union can receive in any subgame-perfect equilibrium.

PROOF:

A proof that there exists a pair of subgame-perfect-equilibrium strategies that support w' as an equilibrium outcome in the first period is given in the proof of Theorem 1. The following is an informal description of the strategies that generate the above equilibrium. In odd-numbered periods, the union offers the contract w' and strikes if this offer is rejected. In even-numbered periods, the union accepts only offers that are greater than or equal to z' but never strikes. If, however, the union deviates from this rule at some point, then the strategies call for both players to play thereafter according to the strategies described in Lemma 2. In other words, a deviation by the union is punished by having it accept the old wage contract of w_0 .

We now show that w' is the maximum wage that the union can obtain in any subgame-perfect equilibrium. Suppose that it is not. Let $w^* > w'$ be the supremum over all wage agreements obtained in any subgame of any subgame-perfect equilibrium. Consider a subgame in which an agreement of $\hat{w} = w^* - \varepsilon$, $\varepsilon < \min[(w^* - w_0)(1 - \delta_u), (w^* - w')(1 - \delta_u\delta_f)]$, is reached. By hypothesis, at least one such subgame must exist. There are two cases to consider.

(i) Suppose this agreement occurs in a subgame in which the firm makes the offer. The following deviation is then profitable for the firm. Let the firm change its offer from \hat{w} to $\phi + \varepsilon'$, where $\phi = w_0(1 - \delta_u) + \delta_u w^*$ and $0 < \varepsilon' < (w^* - w_0)(1 - \delta_u) - \varepsilon$. Note that the union will accept an offer of $\phi + \varepsilon'$, since by rejecting this offer the most that the discounted value of its earnings can be is $w_0 + (1 - \delta_u)^{-1}\delta_u w^*$. However, the discounted value of $\phi + \varepsilon'$ is $w_0 + (1 - \delta_u)^{-1}(\delta_u w^* + \varepsilon')$. The firm gains since by construction, $\phi + \varepsilon' < \hat{w}$.

(ii) Suppose this agreement occurs in a subgame in which the union makes the offer. The following deviation is then profitable for the firm. Let the firm reject the union's offer and, in the following period, independently of whether the union chose

to strike in the previous period, offer the union a wage of $\phi + \varepsilon''$ where $0 < \varepsilon'' < [(1 - \delta_u\delta_f)(w^* - w') - \varepsilon]\delta_f^{-1}$. As shown in (i), the union will accept such an offer. The firm gains since, as can be shown by some algebraic manipulation and recalling that $w^* - \varepsilon > w'$, $F - \hat{w} < \delta_f(F - \phi - \varepsilon'')$.

Intuitively, the reason why this strategy of striking only in odd-numbered periods yields a greater wage contract than the strategy described in Lemma 3 of striking in every period, is that the first strategy creates an asymmetry in each party's costs of rejecting the other's offer. It is now more costly for the firm to reject the union's offer than it is for the union to reject the firm's offer, since rejection of the union's offer leads to a strike (with the consequent loss of profit for the firm), whereas the rejection of the firm's offer still allows the union to earn w_0 .

An alternative interpretation of w' is to note that w' can be written as

$$w' = w_0 + (1 - \delta_f)(F - w_0)(1 - \delta_u\delta_f)^{-1}.$$

That is, w' is equal to w_0 plus the solution to the original Rubinstein game in which the cake is of size $F - w_0$. By employing a strategy of striking only in odd-numbered periods, it is as though the players are bargaining over a cake of size $F - w_0$ and the union is already guaranteed a return of w_0 .

We now characterize the entire set of subgame-perfect-equilibrium wage contracts. Moreover, we show that all these contracts can be generated by Pareto-efficient subgame-perfect-equilibrium strategies.

THEOREM 1: *If $w_0 \leq \delta_u z'$, then any wage contract w such that $w_0 \leq w \leq w'$ can be generated as an equilibrium wage contract with agreement reached in the first period.*

PROOF:

We first introduce the following notation. Suppose that the game has reached period t . For every period $\tau < t$ let D'_τ be a function of the actions taken in that period such

that

$$D'_\tau = \begin{cases} d & \text{if } \tau \text{ is odd and } x_\tau > w'; \\ & \text{if } \tau \text{ is even and } y_\tau \geq z' \text{ but } Q_\tau = N; \text{ or} \\ & \text{if } S_\tau = ns \text{ and } \tau \text{ is odd} \\ nd & \text{otherwise.} \end{cases}$$

D'_τ indicates whether or not the union has deviated in period τ . (Note that, strictly speaking, D'_τ does not capture all possible deviations, since it ignores those offers by the union lower than w' .) If a deviation has occurred in period τ then $D'_\tau = d$; if not, then $D'_\tau = nd$. Similarly, suppose that the play has reached the last move of period t , at which point the union has to decide whether or not to strike. Let D'_t be a function of all actions taken in period t up to the strike decision such that

$$D'_t = \begin{cases} d & \text{if } t \text{ is odd and } x_t > w'; \text{ or} \\ & \text{if } t \text{ is even and } y_t \geq z' \text{ but } Q_t = N \\ nd & \text{otherwise.} \end{cases}$$

Let w be such that the $w_0 \leq w \leq w'$. Then, the following strategies constitute an equilibrium. The union's strategy is as follows:

$$x_1 = w$$

and for t odd and greater than one

$$x_t = \begin{cases} w_0 & \text{if } x_1 > w; \\ & \text{if } S_1 = ns; \text{ or} \\ & \text{if } D'_\tau = d \text{ for some } \tau, 1 < \tau < t \\ w' & \text{otherwise.} \end{cases}$$

When t is even the union's response is

$$Q_t = \begin{cases} Y & \text{if } y_t \geq z'; \\ & \text{if } y_t \geq w_0 \text{ and either } x_1 > w \text{ or } S_1 = ns; \\ & \text{or} \\ & \text{if } D'_\tau = d \text{ for some } \tau, 1 < \tau < t \\ N & \text{otherwise.} \end{cases}$$

Finally,

$$S_t = \begin{cases} ns & \text{if } x_1 > w; \\ & \text{if } S_1 = ns; \\ & \text{if } D'_\tau = d \text{ for some } \tau, 1 < \tau < t; \\ & \text{if } D_t = d; \text{ or} \\ & \text{if } t \text{ is even} \\ s & \text{otherwise.} \end{cases}$$

The firm's strategy is as follows: when t is even it offers

$$y_t = \begin{cases} w_0 & \text{if } x_1 > w; \\ & \text{if } S_1 = ns; \text{ or} \\ & \text{if } D'_\tau = d \text{ for some } \tau, 1 < \tau < t \\ z' & \text{otherwise.} \end{cases}$$

The firm's response in period 1 is

$$R_1 = \begin{cases} N & \text{if } x_1 > w \\ Y & \text{otherwise} \end{cases}$$

and in every odd period t , $t > 1$ it responds according to

$$R_t = \begin{cases} N & \text{if } x_t > w'; \\ & \text{if } x_t > w_0 \text{ and either } x_1 > w \text{ or} \\ & S_1 = ns; \text{ or} \\ & \text{if } D'_\tau = d \text{ for some } \tau, 1 < \tau < t \\ Y & \text{otherwise.} \end{cases}$$

Note that Theorem 1 implies that if w' is an equilibrium, then any w such that $w_0 \leq w \leq w'$ is also obtainable as an efficient subgame-perfect-equilibrium wage contract. Moreover, since w' is the maximum wage obtainable and w_0 is the minimum wage obtainable, this range describes the complete range of wage contracts that can be obtained as subgame-perfect equilibria.

III. Inefficient Equilibria

The purpose of this section is to show that, despite the existence of complete information, it is possible for bargaining to generate inefficient subgame-perfect equilibria. We limit our discussion to strikes that last for an uninterrupted T periods, although it is also possible to have periods of "peaceful" negotiations alternate with periods of strikes.

THEOREM 2: *If \hat{w} is such that*

$$(2) \quad (1 - \delta_f^{1-T})F + \delta_f^{1-T}\bar{z} \geq \hat{w} \geq \delta_u^{-T}w_0$$

then there is a subgame-perfect equilibrium in

*the play of which there is a strike of T periods followed by an agreement of \hat{w} .*⁷

PROOF:

See the Appendix for a formal presentation of the strategies.

We now provide an informal proof of the theorem, in which we limit ourselves to describing the strategies along the equilibrium path and to a discussion of the conditions sufficient for deviations not to occur. In each period prior to $T + 1$, the union makes a nonserious wage offer to the firm (i.e., the union offers a very high wage contract of F , which the firm rejects). In period $T + 1$, if this period is odd-numbered, the union offers $x_{T+1} = \hat{w}$; if it is even-numbered, the union accepts an offer $y_{T+1} = \hat{w}$. The union strikes in every period up to period $T + 1$. Prior to period $T + 1$, the firm also makes nonserious wage offers to the union (i.e., it offers the union very low wage contracts of w_0 , which the union rejects). In period $T + 1$, if this period is even-numbered, the firm offers $y_{T+1} = \hat{w}$; if it is odd-numbered, the firm accepts an offer $x_{T+1} = \hat{w}$.

It obviously would be a Pareto improvement if a settlement of \hat{w} were reached in any of the periods prior to $T + 1$. In fact, there exists a whole range of wage contracts that would be Pareto-improving if agreement on them were reached prior to $T + 1$. These potentially Pareto-improving deviations are blocked, however, by each party's response to deviations: attempts by the firm to "bribe" the union to reach a settlement earlier (by making wage offers such that the union prefers to accept the wage offered that period rather than wait until period $T + 1$ to obtain \hat{w}) are thwarted by having the strategies require both parties to play thereafter the equilibrium of Lemma 3 (which the union prefers to \hat{w}). That is, the union rejects the firm's offer, strikes, and in the following period offers the firm a wage contract of \bar{w} , which the firm then accepts. If, on the other hand, the union were to

deviate and attempt to reach an earlier settlement by offering the firm a wage contract that the latter preferred over obtaining an agreement of \hat{w} in period $T + 1$, or if the union simply decided not to strike, these deviations are thwarted by having the strategies require both parties to play thereafter the status quo wage equilibrium w_0 given in Lemma 2 (the best equilibrium outcome for the firm). That is, the firm would reject this offer, and next period it would offer the union a wage contract of w_0 , which the latter would then accept. The union's failure to strike likewise would lead to an agreement of w_0 in the following period. The actual \hat{w} agreement in period $T + 1$ is supported by the subgame-perfect-equilibrium strategies described in the proof of Theorem 1. That is, assuming no deviations have occurred prior to period $T + 1$, deviations at or after period $T + 1$ require both parties to play according to the strategies given in the proof of Theorem 1.

It is now easier to see how the conditions given in (2) are generated. The union always can obtain a wage contract of w_0 immediately, since the union always can choose not to strike and receive w_0 independently of any actions taken by the firm. Thus, in order for the union to be willing to strike for T periods, it should prefer to receive 0 for T periods, followed by a wage of \hat{w} thereafter, rather than to receive w_0 each period commencing in period 1. That is,

$$\delta_u^T \hat{w} \geq w_0$$

(i.e., \hat{w} must be sufficiently large).

If the firm were to attempt to reach an immediate settlement by offering the union $\bar{z} + \varepsilon$, $\varepsilon > 0$, it would not be subgame-perfect for the union to reject this offer, since next period it would receive \bar{w} , and $\bar{z} + \varepsilon > \delta_u \bar{w}$. Thus, in order for this deviation not to be performed by the firm, it must prefer to suffer the T periods of strike, followed by an agreement of \hat{w} , rather than to achieve an agreement of \bar{z} immediately (since \bar{z} is the lowest wage contract that can "bribe" the union). That is,

$$F - \bar{z} \leq \delta_f^{T-1} (F - \hat{w})$$

⁷It is actually possible to have a wider range for \hat{w} by substituting z' for \bar{z} in (2) and using the odd-period-only strikes equilibrium (described in Lemma 4).

or, rearranging terms,

$$(1 - \delta_f^{1-T})F + \delta_f^{1-T}\bar{z} \geq \hat{w}$$

(i.e., \hat{w} must be sufficiently small).

These are the only binding constraints on the size of \hat{w} , since any further deviations will only be less profitable than those just described.

Many models of bargaining under incomplete information have the feature that, even if an agreement is not reached immediately in equilibrium, the delay in reaching an agreement becomes arbitrarily small as the (exogenously given) time interval between two successive offers becomes arbitrarily small. In other words, when periods are short, allowing agents to alternate offers quickly, there is essentially no delay in reaching an agreement. This result is also known as the Coase conjecture.⁸

An important feature of our model is that shorter periods not only imply that agents alternate offers more rapidly, but also they accordingly shorten the length of a strike, given a decision to strike for a period. (If this were not the case, that is, if players could make offers and counteroffers quickly but the duration of a strike commitment remained unchanged, then all our previous results would go through trivially). However, it is easy to show that, even when the strike period becomes arbitrarily small, there exist equilibria with lengthy strikes. The reason for this is that strikes are not a signalling device for either player in our model. The union strikes because not doing so means that it will obtain a lower wage. The maximum length of strike time depends solely on the difference in payoffs that the union can obtain by striking as compared to not striking and not on any information revealed through delay; delay is no longer a mechanism by which different types separate themselves.

⁸Some notable exceptions are Admati and Perry (1987), Ausubel and Deneckere (1989), Peter C. Cramton (1989), and Hart (1989).

IV. Extensions

A. Lockouts

Thus far, we have examined equilibria that emerge when only the union is allowed to engage in actions other than offers, rejections, and acceptances. We would now like to ask how our results are affected if the firm is allowed to engage in lockouts. In order to simplify our computations, we assume that workers earn zero if they are locked out.⁹

If we start by examining a game in which only lockouts are feasible (the union is not allowed to strike), it is interesting to note that the equilibrium outcome obtained when the firm follows the strategy of locking out the union in every even-numbered period in which an agreement is not reached (i.e., a strategy analogous to the one described for the union in Lemma 4) now yields

$$\bar{w} = \frac{(1 - \delta_f)w_0}{1 - \delta_u\delta_f}$$

$$\bar{z} = \frac{\delta_u(1 - \delta_f)w_0}{1 - \delta_u\delta_f}$$

where \bar{w} is the wage contract obtained if the union commences the bargaining procedure and \bar{z} is obtained if the firm starts.¹⁰ This strategy again transforms the game into Rubinstein's (1982) original game, but now w_0 is the size of the cake being bargained over. Just as the odd-period-strike equilibrium allowed the union to bargain with the firm over the latter's right to earn $F - w_0$, the even-period-lockout strategy allows the firm to bargain with the union over the latter's right to work and receive w_0 . Thus,

⁹In reality, workers often receive unemployment compensation. This modification would not qualitatively affect our results.

¹⁰The condition for this to be a subgame-perfect equilibrium is

$$w_0 \geq F(1 - \delta_f)(1 - \delta_u\delta_f)[1 - \delta_u\delta_f - \delta_f(1 - \delta_f)]^{-1}.$$

this agreement yields the union a wage contract smaller than the status quo contract.

If we allow both lockouts and strikes (one can think of these decisions as following a rejection of an offer and occurring either simultaneously or sequentially), it is possible to have equilibria in which strikes, for example, alternate with lockouts along the equilibrium play before a final agreement is reached. These inefficient equilibria are sustained by having the strategies require the parties to play the w' equilibrium if the firm deviates (i.e., the best outcome for the union) and the \bar{w} equilibrium if the union deviates (the best outcome for the firm).

B. Multiple Contract Renegotiations

We now extend our model to allow for contracts that are repeatedly, potentially infinitely, renegotiated. We suppose that contracts are periodically renegotiated every M periods (periodicity is assumed for notational simplicity) after a contract has been established. All of the equilibrium outcomes described in the previous sections are also equilibrium outcomes in this modified setting [the strategies must now require that, after the first contract renegotiation (w^*) is concluded, the union will only accept and offer wage contracts of w^* or above and will never strike, and the firm will only accept and offer wage contracts of w^* and below]. In addition, we can now show that, unlike in the previous sections, the new equilibrium contract need not necessarily offer the union a wage greater than or equal to w_0 . As long as the union expects there to be a future contract in which its new wage will be sufficiently high so as to compensate it for the periods in which it worked for a lower wage, a wage contract lower than w_0 can be accepted as part of a subgame-perfect equilibrium. An example follows.

Example: Consider the following equilibrium play: in the first period, the union offers a wage contract of $p < w_0$, which the firm accepts. This contract comes up for renegotiation M periods later. Assuming $M + 1$ is odd, the union then offers a wage contract of $q > w_0$, which the firm accepts.

This outcome is supported by having the two parties play, as of the subgame following the deviation, the equilibrium strategies of Lemma 3 (that support \bar{w}) if the firm deviates and having them play the equilibrium strategies of Lemma 2 (that support w_0 if $t = 1$ and support p if $t > 1$) if the union deviates. In order for deviations not to be profitable, therefore, we must have the union prefer the equilibrium outcome to obtaining a wage contract of w_0 forever, that is,

$$(q - p)\delta_u^M + p \geq w_0.$$

Also, if the firm rejects the union's offer of p , the union must prefer to strike and obtain a wage contract of \bar{z} next period to working that period and thereafter for a wage of w_0 . Hence,

$$\delta_u \bar{z} \geq w_0.$$

V. Conclusion

This paper has shown that bargaining between two agents may be inefficient even if both parties are completely rational and fully informed. In our specific case of a union and a firm negotiating a new wage contract, we have shown that this process may involve periods of strikes. Hence, neither bounded rationality nor incomplete information is a necessary condition for a consistent theory of strikes. The length of time for which the union can strike depends on the status quo wage—the wage specified by the preexisting contract—and on the profitability of the firm. The lower the status quo wage and the more profitable the firm, the greater the maximum length of time for which the union may strike in equilibrium. The ability of the union to strike, even in those equilibria in which the union does not actually strike along the equilibrium play, can only improve the union's position at the bargaining table. Thus, the union's threat to strike may be credible despite the cost to the union of carrying out such a threat. Furthermore, even if the time separating bargaining periods becomes arbitrarily small, strikes can still occur in real time (i.e., lengthy strikes are still possible).

We have shown that our model can be extended to include multiple recontracting opportunities and the ability of the firm to engage in lockouts. Another interesting extension would be to include uncertainty in the form of shocks to the firm's revenue function through technology or price changes. If these shocks were perfectly observable to all parties, contracts could be renegotiated in the event of a shock. The range of parameter values that permit inefficient equilibria would be greater for positive shocks than for negative ones, which is suggestive of the empirical finding that strikes are procyclical.

Finally, our paper's main result—that bargaining between two parties may result in inefficient outcomes—may justify the existence of Pareto-inferior phenomena other than strikes. Observed inefficiencies in the international arena (e.g., the existence of tariff wars or protracted debt negotiations interspersed with periods of debt moratoria) may also be explained by our model. In particular, our model can offer an explanation for why two completely rational countries may engage in war although their disagreements could be settled via the much less costly process of diplomacy.

APPENDIX

We provide a pair of subgame-perfect equilibrium strategies that generate strikes for T periods followed by an agreement of \hat{w} in period $T+1$. We assume here that T is even-numbered.

For every t , $1 \leq t \leq T+1$, let AD_t be a function of the history of play up to (but not including) period t such that

$$AD_1 = nd$$

and for $t > 1$,

$$AD_t = \begin{cases} nd & \text{if for every } \tau, 1 \leq \tau < t, S_\tau = s; \text{ for every odd } \tau, x_\tau = F; \text{ and, for every even } \tau, y_\tau = w_0 \\ df & \text{if there exists some even } \tau' < t \text{ such that } AD_{\tau'} = nd \text{ but } y_{\tau'} > w_0, S_{\tau'} = s, \text{ and } D_\tau = nd \text{ for all } \tau, \tau' < \tau < t \\ du & \text{otherwise} \end{cases}$$

where D_τ is the equivalent of D'_τ with the substitution of \bar{w} for w' , \bar{z} for z' , and $S_\tau = ns$ for all $\tau < t$.

The function AD_t indicates whether, prior to period t , any of the players deviated from equilibrium play and identifies this player. If $AD_t = nd$, no deviation has occurred; if $AD_t = df$, the firm has deviated and the union has not; and if $AD_t = du$, the union has deviated.

For every t , $1 \leq t < T+1$, let DD_t be a function from the history of play at period t such that

$$DD_t = \begin{cases} d & \text{if } AD_t = nd \text{ and } t \text{ is odd and } x_t < F; \\ & \text{if } AD_t = df \text{ and either } t \text{ is odd and } x_t > \bar{w} \text{ or } t \text{ is even and } y_t \geq \bar{z} \text{ but } Q_t = N; \text{ or} \\ & \text{if } AD_t = du \\ nd & \text{otherwise.} \end{cases}$$

DD_t indicates whether or not the union has deviated in or prior to period t before its decision of whether or not to strike.

For $t > T+1$, let BD_t be a function of the history of play up to (but not including) period t , such that

$$BD_t = \begin{cases} df & \text{if } AD_{T+1} = df \text{ and } D_\tau = nd \text{ for all } \tau, T+1 \leq \tau < t; \text{ or} \\ & \text{if } AD_{T+1} = nd, x_{T+1} \leq \hat{w}, S_{T+1} = s, \text{ and } D_\tau = nd \text{ for all } \tau, T+1 < \tau < t \\ du & \text{otherwise.} \end{cases}$$

The function BD_t indicates whether the union or only the firm has deviated from the equilibrium rule.

The union's strategy is

$$x_1 = F$$

and in every odd-numbered t , $1 < t < T+1$, it offers

$$x_t = \begin{cases} F & \text{if } AD_t = nd \\ \bar{w} & \text{if } AD_t = df \\ w_0 & \text{otherwise.} \end{cases}$$

In period $T + 1$, it offers

$$x_{T+1} = \begin{cases} \hat{w} & \text{if } AD_{T+1} = \text{nd} \\ \bar{w} & \text{if } AD_{T+1} = \text{df} \\ w_0 & \text{otherwise.} \end{cases}$$

and for every odd-numbered t , $t > T + 1$,

$$x_t = \begin{cases} \bar{w} & \text{if } BD_t = \text{df} \\ w_0 & \text{otherwise.} \end{cases}$$

For $t < T + 1$, the union's response is

$$Q_t = \begin{cases} Y & \text{if } y_t \geq \bar{z}; \text{ or} \\ & \text{if } y_t \geq w_0 \text{ and } AD_t = \text{du} \\ N & \text{otherwise.} \end{cases}$$

For $t > T + 1$, the union's response is

$$Q_t = \begin{cases} Y & \text{if } y_t \geq \bar{z}; \text{ or} \\ & \text{if } y_t \geq w_0 \text{ and } BD_t = \text{du} \\ N & \text{otherwise.} \end{cases}$$

For $t < T + 1$, the union's strike decision is

$$S_t = \begin{cases} \text{ns} & \text{if } DD_t = d \\ s & \text{otherwise} \end{cases}$$

and in period $T + 1$,

$$S_{T+1} = \begin{cases} \text{ns} & \text{if } AD_{T+1} = \text{du}; \\ & \text{if } AD_{T+1} = \text{df} \text{ but } x_{T+1} > \bar{w}; \text{ or} \\ & \text{if } AD_{T+1} = \text{nd} \text{ but } x_{T+1} > \hat{w} \\ s & \text{otherwise.} \end{cases}$$

For every $t > T + 1$,

$$S_t = \begin{cases} \text{ns} & \text{if } BD_t = \text{du}; \text{ or} \\ & \text{if } BD_t = \text{df} \text{ but } D_t = d \\ s & \text{otherwise.} \end{cases}$$

where D_t is the equivalent of D'_t with the substitution of \bar{w} for w' and \bar{z} for z' .

The firm's strategy is as follows: when t is even and $t < T + 1$, it offers

$$y_t = \begin{cases} \bar{z} & \text{if } AD_t = \text{df} \\ w_0 & \text{otherwise} \end{cases}$$

and when $t > T + 1$, it offers

$$y_t = \begin{cases} \bar{z} & \text{if } BD_t = \text{df} \\ w_0 & \text{otherwise.} \end{cases}$$

When t is odd and $t < T + 1$, the firm's response is

$$R_t = \begin{cases} Y & \text{if } x_t \leq w_0; \text{ or} \\ & \text{if } x_t \leq \bar{w} \text{ and } AD_t = \text{df} \\ N & \text{otherwise} \end{cases}$$

and in period $T + 1$, it responds

$$R_{T+1} = \begin{cases} N & \text{if } x_{T+1} > \bar{w}; \\ & \text{if } x_{T+1} > \hat{w} \text{ and } AD_{T+1} = \text{nd}; \text{ or} \\ & \text{if } x_{T+1} > w_0 \text{ and } AD_{T+1} = \text{du} \\ Y & \text{otherwise.} \end{cases}$$

In every odd-numbered t , $t > T + 1$, the firm responds according to

$$R_t = \begin{cases} N & \text{if } x_t > \bar{w}; \text{ or} \\ & \text{if } x_t > w_0 \text{ and } BD_t = \text{du} \\ Y & \text{otherwise.} \end{cases}$$

An Experimental Analysis of Strikes in Bargaining Games with One-Sided Private Information

By ROBERT FORSYTHE, JOHN KENNAN, AND BARRY SOPHER*

We study two-player pie-splitting games in which one player knows the pie and the other knows only its probability distribution. We compare treatments in which incentive-efficient strikes (disagreements) are possible with alternatives in which efficiency forbids strikes. We find that incentive-efficiency is very helpful in explaining when strikes occur. There is also evidence of substantial heterogeneity in the subjects' altruism and in their risk preferences. This means that the common-knowledge assumptions of game theory cannot be controlled in experiments; but in our experiments the main theoretical conclusions seem robust to violations of these assumptions. (JEL 026, 215)

Recent theoretical analyses of strikes have emphasized the potential importance of private information in rationalizing the apparent inefficiencies associated with strike activity. The basic idea is that although strikes are not Pareto optimal *ex post* they may be Pareto optimal *ex ante*, in the sense that every alternative leaves one of the bargainers worse off in some contingency which cannot be ruled out on the basis of information that is common knowledge.

There are two serious difficulties with private-information bargaining models. First, there is an obvious problem in extracting empirical implications, since some of the relevant data, by definition, are not observable. Second, even simple models present formidable technical problems, so that it is necessary to make assumptions that are not literally credible in order to obtain results.

For example, strategic analyses proceed on the assumption that the timing of offers and counteroffers is governed by a procedure that is imposed arbitrarily.

A sensible response to these difficulties is to attempt to build simple models that give reasonably accurate descriptions of behavior observed in experiments, where the effects of private information can be measured directly. A particular goal of this work is to identify predictions that are robust with respect to the simplifying assumptions used in theoretical modeling.

This paper describes the result of a bargaining experiment involving a set of pie-splitting games between two players. The pie is a sum of money which takes on one of two values (good and bad) with known probabilities. One player knows the realized value of the pie, while the other knows only the probabilities of the two pie sizes. The players do not meet face-to-face, but they can negotiate by passing nonbinding handwritten messages to each other and by making binding offers to split the pie in a particular way. If agreement is not reached within 10 minutes, then neither bargainer gets anything.

If the uninformed bargainer has the right to issue an ultimatum in this game, as in the analysis of Drew Fudenberg and Jean Tirole (1983), then he can obtain the bad pie for sure, or he can obtain the good pie when it is there and zero otherwise. A self-

ish and risk-neutral uninformed bargainer will demand the good pie if his expected earnings from doing so exceed the size of the bad pie. We call this the *strike condition*: if it holds, the bargainers will fail to agree whenever the bad pie is drawn. In our experiment, however, no one has the right to make all-or-nothing demands. An alternative bargaining structure, proposed by Myerson (1984), allows the bargainers to negotiate over the set of direct mechanisms, which specify whether a strike should occur and how much each bargainer should get, as a function of the informed bargainer's announcement of the pie size. In this context, there is a large class of (interim incentive-) efficient mechanisms that do not involve a strike: any mechanism that gives the uninformed bargainer a fixed amount will do, provided each player gets a nonnegative payoff. If the strike condition holds, then there are also efficient mechanisms involving a strike in the bad state. Further, the incidence of strikes can be predicted by adopting a *random-dictator* (RD) axiom, which asserts that the bargainers will agree to a fair mixture of the mechanisms that each would unilaterally impose.

Both of these theoretical models suggest that strikes should occur more often in our experiment when the strike condition holds and when the pie is small. This prediction worked well, even though our experimental setting did not correspond exactly to either model. We also found, however, that strikes sometimes occurred in the good state, and also in the bad state, when the strike condition did not hold. Moreover, the two games in the experiment in which the strike condition was on gave quite different strike-incidence results. The RD axiom implies that strike incidence should depend only on the strike condition and not on any other parameters: this prediction failed in our experiment.

We also conducted an additional experiment designed to test the RD axiom directly and to calibrate the results of the bargaining experiment. In the RD experiment, both the informed and uninformed bargainers submitted all-or-nothing demands specifying the amount that the uninformed player

would receive. One of these demands was randomly chosen, and both players were paid accordingly if the selected demand was feasible (i.e., did not exceed the size of the pie). In these games, the informed bargainer should always keep the whole pie, while the uninformed bargainer should demand the good pie if the expected earnings from doing so exceed the size of the bad pie. Thus, there should always be a strike whenever the strike condition is on, the pie is small, and the uninformed bargainer's demand is chosen.

Comparing the RD games with the bargaining games, we found that the strike-incidence results were remarkably close. The RD results suggest that the unexplained variation in strike incidence in the bargaining games is due, to some extent, to violations of the risk-neutrality assumption. There is strong evidence of heterogeneity in the subject population, with a majority of risk-neutral types, but with substantial minorities of both risk-averse and risk-seeking types. Further, while the typical player was selfish, there was some altruistic behavior, which had a substantial effect on the outcomes.

In a series of experiments initiated by Alvin Roth, Michael Malouf, and Keith Murnighan (1979),¹ it has been found that the incidence of strikes in bargaining games tends to be related to the distribution of private information that is theoretically irrelevant. In these experiments, players bargained over lottery tickets that determined the probability of winning a prize, which was different for each player. If each player maximizes expected utility, knowledge of the prizes should be irrelevant in the bargaining game, and since both players know everything that is relevant to the game, there is no reason for strikes to occur. In fact, however, it was found that some strikes invariably occurred, and strike incidence was higher when it was not commonly known

¹See also Roth and Malouf (1979), Malouf and Roth (1981), Roth and Murnighan (1982), and Roth and Francoise Schoumaker (1983); for a review of this work, see Roth (1988).

that the player with the smaller prize knew both prizes. The main difference between this line of research and the experiments reported here is that we focus on the effect of private information that is relevant, according to the theory, because of incentive-compatibility constraints. In our setting, the theory includes strikes, and we can test whether the observed variations in strike incidence correspond to the theoretical predictions.

I. Efficient Bargaining Mechanisms

It is not possible to provide a complete strategic analysis of the bargaining games we conducted, since players could freely exchange messages. Instead, we consider two models that are abstractions of these games. The first is an ultimatum game, that is, a game in which one player can make an all-or-nothing demand which the other player must accept or reject. The second is a model in which players bargain over mechanisms. Both models lead to the same condition for efficient strikes.

We consider a class of pie-splitting games between two players, in which one player has private information. The pie is a sum of money, π , which takes the values π_g (good) with probability p and π_b (bad) with probability $1 - p$. One player already knows the realization of π when negotiations begin, while the other knows only the probability distribution from which π has been drawn. A fixed period of time is allowed for negotiation, and if agreement is not reached during this time, then the pie is lost. The period is short enough so that delaying an agreement is not costly (provided that agreement is reached before the deadline). It is also assumed that both players are selfish expected-income maximizers.

This is a simple example of a class of games that have been studied extensively in the bargaining literature.² A basic result is

that if the uninformed player has the ability to make nonnegotiable demands, then he will demand π_g (play "tough" in the language of Fudenberg and Tirole [1983]) if the condition $p\pi_g > \pi_b$ holds, and otherwise he will demand π_b (play "soft"). This is the strike condition: if it holds, the bargainers will fail to agree whenever the bad pie is drawn. This result is sensitive to the rules of bargaining, however: if the informed player could make nonnegotiable demands, for example, he would keep the pie in either state, and strikes would not occur. More generally, if neither player can commit to a particular bargaining position, then the outcome depends on each player's cost of delay, on the rules governing the timing of offers and counteroffers, and on which of many possible equilibria is reached. Still, a reasonable conjecture is that if the strike condition does not hold then strikes will not occur in equilibrium.

Because of the unconstrained messages which pass between the players, our bargaining game is too complicated to allow a detailed strategic analysis. However, by the revelation principle, any Nash equilibrium of this game is equivalent to some direct mechanism, which specifies whether a strike should occur and how much each bargainer should get as a function of the informed bargainer's announcement of the size of the pie. We will argue that if the equilibrium is not incentive-efficient then the uninformed bargainer will make an offer that the informed bargainer cannot afford to refuse. Thus, strikes will not occur unless they can be construed as part of an incentive-efficient mechanism.

Following Roger Myerson (1979, 1984), we analyze efficiency by assuming that the bargainers negotiate inscrutably over the set of direct mechanisms.³ We consider mechanisms that work as follows. The informed bargainer first announces that the state is good or bad. The uninformed bargainer can

²See, for example, Joel Sobel and Ichiro Takahashi (1983), Fudenberg and Tirole (1983), and Peter Cramton (1984). A critical review of this literature, as it pertains to the interpretation of strike data, appears in Kennan and Robert Wilson (1989).

³A detailed discussion of this model was presented in Kennan (1986), and extensions to the case of two-sided private information were discussed in Kennan (1987).

then reduce the pie by a known fraction $1 - \gamma$ (interpreted as the probability of disagreement or as the duration of a strike), leaving $\gamma_g \pi$ or $\gamma_b \pi$, according to the announcement made by the informed bargainer. The uninformed bargainer receives x_g or x_b , and the informed bargainer receives the rest of the pie. Thus, a mechanism μ is defined by four parameters (γ_j and x_j for $j = b, g$). A crucial assumption here is that the players can reach an agreement that commits them to implement a mechanism, even though one or both of them might wish to tear up the agreement immediately after it has been signed.

Incentive compatibility requires that it is optimal for the informed bargainer to tell the truth. The payoffs and the resulting truth-telling conditions can be tabulated as follows:

Valuation	Truth \geq Lie
Good	$\gamma_g \pi_g - x_g \geq \gamma_b \pi_g - x_b$
Bad	$\gamma_b \pi_b - x_b \geq \gamma_g \pi_b - x_g$

Thus, a mechanism is incentive-compatible (IC) if

$$(1) \quad (\gamma_g - \gamma_b) \pi_b \leq x_g - x_b \leq (\gamma_g - \gamma_b) \pi_g.$$

An IC mechanism is feasible if it is individually rational (IR), in that it gives nonnegative expected payoffs to each player in each state.

Incentive-efficiency⁴ is defined in terms of a Pareto ordering (over the set of feasible mechanisms) that respects the preferences of all types of all players, even though only one type of each player is actually present. In our context, this means that a mechanism is efficient if it is Pareto optimal for the set of three agents including the uninformed player, the informed player with the good pie, and the informed player with the bad pie.

We concentrate on the implications of the efficiency criterion for the incidence of "strikes," defined as a failure of the bar-

gainers to agree on a division of the pie. It is easy to show that strikes in the good state are not efficient: $\gamma_g = 1$. Indeed, $\gamma_g \geq \gamma_b$ by the IC constraints, so if $\gamma_g = 1 - \delta < 1$, we can define a new mechanism μ^* with $\gamma_g^* = 1$, $\gamma_b^* = \gamma_b + \delta$, $x_g^* = x_g$, and $x_b^* = x_b$. The mechanism μ^* does not affect the uninformed bargainer's expected payoff, but it increases the informed bargainer's payoff by $\delta \pi_g$ and $\delta \pi_b$ in the good and bad states, respectively, so the original mechanism cannot be efficient.

If γ_b can be increased without violating the incentive-compatibility constraint, the uninformed bargainer is unaffected, as is the informed bargainer in the good state, while the informed bargainer is made better off in the bad state. Thus, efficiency requires that the right-hand inequality in the incentive-compatibility constraint must hold with equality, that is,

$$(2) \quad x_g - x_b = (1 - \gamma_b) \pi_g.$$

We now show that the condition $p \pi_g > \pi_b$, which indicates that the uninformed bargainer would play tough in the noncooperative game, also determines whether efficient strike mechanisms exist in the cooperative game. Consider a mechanism $\mu = (\gamma_g, x_g, \gamma_b, x_b)$ which satisfies (2), with $\gamma_b < 1$. If strikes are not efficient, there is another mechanism which strictly dominates μ . Call this mechanism $\mu^* = (1, x_g^*, \gamma_b + \delta, x_b + d)$, where x_g^* is constructed to satisfy (2). Let ΔV_g , ΔV_b , and ΔU denote the resulting changes in expected payoffs to the informed bargainer in the good and bad states and to the uninformed bargainer. Then,

$$\Delta V_g = \pi_g \delta - d$$

$$\Delta V_b = \pi_b \delta - d$$

$$\Delta U = -p \pi_g \delta + d.$$

If all three of these changes are nonnegative and one is positive, then δ is not zero, and

$$\pi_g \delta \geq d \geq p \pi_g \delta$$

$$\pi_b \delta \geq d \geq p \pi_g \delta.$$

⁴This is "interim incentive efficiency," in the language of Bengt Holmstrom and Myerson (1983).

The first set of inequalities implies that δ is nonnegative, and (since δ is not zero) the second set then implies $\pi_b > p\pi_g$. In this case, strikes cannot be efficient, since values of δ and d can be chosen such that μ^* dominates μ . If the strike condition $p\pi_g > \pi_b$ holds, however, efficient strike mechanisms exist; in fact, any individually rational mechanism that satisfies (2) is efficient in this case. This also means that even when the strike condition holds there is a large class of efficient mechanisms that do not involve a strike, namely the class of IR mechanisms which give the uninformed bargainer a transfer that does not depend on the state.

Strike Incidence

So far, we have identified a necessary condition for efficient strikes, but we have not predicted the actual incidence of strikes when this condition holds. In fact, given that efficient strike mechanisms exist, the incidence of strikes depends on which mechanism is selected. Again following Myerson (1984), a sharp prediction can be made by imposing a random-dictator (RD) axiom, which asserts that the bargainers will agree to a fair mixture of the mechanisms that each would impose if given dictatorial power over the set of feasible mechanisms.

The RD axiom implies that strikes will occur with probability $\frac{1}{2}$ when the strike condition is satisfied and the bad pie is drawn. Thus, when $p\pi_g > \pi_b$ the uninformed bargainer would impose the mechanism $\mu = (1, \pi_g, 0, 0)$, which is an all-or-nothing demand for the big pie. When $p\pi_g < \pi_b$ the uninformed bargainer prefers π_b with certainty, so he will impose the mechanism $\mu = (1, \pi_b, 1, \pi_b)$, which is a fixed-transfer mechanism with no strikes. If the informed bargainer is the dictator, he will impose the mechanism $\mu = (1, 0, 1, 0)$, in which the uninformed bargainer always receives 0 and strikes never occur.

Randomizing equally between these two extremes gives the mechanisms

$$\mu = (1, \frac{1}{2}\pi_g, \frac{1}{2}, 0) \text{ when } p\pi_g > \pi_b$$

and

$$\mu = (1, \frac{1}{2}\pi_b, 1, \frac{1}{2}\pi_b) \text{ when } p\pi_g < \pi_b.$$

Thus, when the strike condition is on, this solution predicts that the incidence of strikes will be 50 percent when the pie is small, for all values of p , π_g , and π_b that satisfy $p\pi_g > \pi_b$. When the pie is big or when the strike condition is off, no strikes should occur.⁵

To sum up, the analysis of efficient bargaining mechanisms leads to clear predictions about the incidence of strikes. If a mechanism is not efficient, then either player can (without leaking information) propose an alternative that improves the outcome for both players. This implies that, if efficient strike mechanisms do not exist, then strikes will not occur. Thus, the theory predicts that strikes will occur only if the condition $p\pi_g > \pi_b$ holds, and then only if the bad pie is drawn. Further, imposing the RD axiom leads to the prediction that strikes should occur with probability $\frac{1}{2}$ when the strike condition is on and the pie is small.

II. The Experiments

A. Choice of Parameters

We used four different parameter sets, as shown in Table 1. Game I was run twice in the bargaining experiment; in game Ia there were two sessions, and in game Ib there were three sessions, as described below. In games I and II the strike condition is on, and in games III and IV the condition is off. Some early results led us to conjecture that strikes might be averted if the informed player could afford to offer half of the big pie, even when the small pie had actually been drawn. Thus, we chose parameters such that in games I and III the small pie is less than half of the big pie, while the opposite is true in games II and IV. In all of the games except Ib the participants played 10 separate games; in Ib the participants played 15 separate games.

⁵This solution is the same as Myerson's (1984) neutral bargaining solution for the simple bargaining games we consider here.

TABLE 1—PARAMETERS

Parameter set	p	π_g	π_b	$p\pi_g > \pi_b?$	Number of games played
Ia	$\frac{1}{2}$	6.00	1.00	yes	10
Ib	$\frac{1}{2}$	6.00	1.00	yes	15
II	$\frac{3}{4}$	3.90	2.30	yes	10
III	$\frac{1}{2}$	4.20	2.80	no	10
IV	$\frac{1}{4}$	6.80	2.40	no	10

B. Procedures

The experimental subjects were students recruited from undergraduate classes in economics at the University of Iowa. Each subject played 10 or 15 separate games against different anonymous opponents, with the same parameters (p, π_g, π_b) in each game. The experiments were conducted in sessions of five games each, held on two or three consecutive evenings. To encourage attendance at the subsequent sessions, earnings were withheld until the final session was completed. To eliminate incentives for reputation formation, participants were told nothing about their opponents' behavior in previous games. The participants were given no opportunity to see their opponents, before, during, or after the experiment.

We used two connecting rooms, each of which could accommodate up to seven subjects. Each participant alternated between being informed and uninformed in successive periods: the individuals in room A were uninformed in odd-numbered periods and informed in even-numbered periods, with the opposite designations in room B. The work of K. Binmore, A. Shaked, and J. Sutton (1984, 1985) suggests that allowing experimental subjects to play both sides of a bargaining game tends to eliminate an apparent inclination toward "fair" outcomes. On the other hand, each subject faced just one parameter set and, thus, had ample opportunity to learn the game.

In games Ia, II, III, and IV, two groups of five or six individuals each were recruited for each room; label these groups as A1, A2, B1, and B2. In the first session, each person in group A1 played a sequence of five one-shot games against different oppo-

nents from group B1, while group A2 played against group B2. In the second session, each person in group A1 played an additional sequence of five one-shot games against different opponents from group B2, while group A2 played against group B1. Game Ib was similar, except that there were three sessions, and three groups of seven individuals were recruited for each room. The rotation of groups across sessions was analogous to the other games: A1 played B1, then B2, then B3, etc.

At the beginning of each session, each participant was given a set of instructions (see Appendix A). The experimenter read the instructions aloud and answered questions. The size of the pie was determined at the start of each bargaining period by having the informed bargainer draw from a box containing N (50, 60, or 100) poker chips, including pN good (blue) chips and $(1-p)N$ bad (white) chips. Thus, it was presumably common knowledge that the probability of the good pie was p .

C. The Bargaining Experiment

In the bargaining games, the players negotiated over the amount of money that the informed bargainer would transfer to the uninformed bargainer; this transfer was not contingent on the informed bargainer's information. Each bargaining period lasted 10 minutes, during which free two-way communication was allowed by means of handwritten messages. The subjects gave messages to the monitor in their room, who passed them to the other bargainer via the monitor in the other room. A timekeeper was placed between rooms to mark the time on each message as it passed through and to ensure

that messages did not cross in the mail. Typically, a message arrived about 15 seconds after it was sent.

Each subject was provided with a large stock of forms on which to write messages. The forms included a space where formal proposals could be made and accepted. Once a formal proposal was made, it could be held by the other bargainer and accepted at any time before the end of the bargaining period. The first accepted proposal to reach the timekeeper determined the outcome for the period; if no proposal was accepted before the end of the period, each bargainer received zero for the period. The uninformed bargainer was never told the size of the pie that the informed bargainer had drawn, even when the period was over.

As can be seen from this description, the bargaining experiment was not faithful to the details of Myerson's model, since it did not explicitly involve bargaining over mechanisms. We take the view that the model is intended as an abstract approximation to realistic bargaining processes and ask whether this approximation will deliver useful predictions in a natural bargaining game.

Our experimental design also does not allow implementation of the full set of feasible mechanisms, but it does cover an interesting subset. The main restriction is that γ must be either 0 or 1 in the bad state. Efficiency requires in any case that there is no strike in the good state, so $\gamma_g = 1$. If the strike condition holds, then the mechanism determined by $\gamma_g = 1$, $\gamma_b = 0$, $x_g = \pi_g$, and $x_b = 0$ is efficient, and this would be optimal for the uninformed bargainer if he could dictate the mechanism. On the other hand, if a mechanism does not involve a strike, then incentive compatibility requires that the transfers x_b and x_g be equal. Therefore, our simplified design includes the most obvious mechanisms involving strikes, as well as all the relevant mechanisms in which there are no strikes.

D. The Random-Dictator Experiment

The RD games followed the same procedures, but instead of negotiating, each player submitted a single proposal that specified the amount the uninformed player should

receive. Then, the uninformed player drew from a box containing 50 red and 50 white chips to determine which player's proposal would dictate the outcome. If the selected proposal was not feasible (e.g., if π_b was drawn and the uninformed player demanded more than this), then neither player received anything. In tabulating the data, we used the proposals of both players, regardless of which player's proposal was randomly chosen.

III. Results: Strike Incidence

The analysis in Section I implies that strikes should occur only when the strike condition $p\pi_g \geq \pi_b$ holds and when π_b is drawn, if all players are selfish expected-income maximizers who bargain inscrutably over enforceable mechanisms. Thus, strikes can sometimes be construed as efficient when the size of the pie is not common knowledge. But if the incentive-efficiency principle is to serve as a general explanation for bargaining conflicts, the predictions made by this principle should not depend substantially on details of the bargaining process. In the bargaining experiment reported here, we examine a natural but complicated bargaining game to see if it may be reduced to a simple analysis of efficient mechanisms. Thus, we ask whether incentive efficiency helps explain the variations in strike incidence across the different states and parameter sets of the bargaining experiment.

We will show that incentive efficiency explains some, but not all, of the variation in strike incidence in the bargaining experiment. It might be that some of the unexplained variation occurred because the players were not selfish or not risk-neutral, as we assumed. We check this by comparing the bargaining results with the results of the RD games, in which any systematic discrepancy between predictions and outcomes can only be due to misspecification of the players' objectives. Alternatively, it might be that the free exchange of messages and proposals in the bargaining experiment introduced important strategic complications that were not captured in the abstract model of mechanism bargaining. In the next section,

TABLE 2—INCIDENCE OF STRIKES IN BARGAINING GAMES

Game	Pie size	Session 1	Session 2	Session 3	All sessions
Ia ($p = 0.5$)	\$1.00	48.4% (9.0%) (15/31)	29.6% (8.8%) (8/27)		39.7% (6.4%) (23/58)
	\$6.00	12.5% (6.9%) (3/24)	9.1% (6.3%) (2/22)		10.9% (4.6%) (5/46)
Ib ($p = 0.5$)	\$1.00	28.6% (6.0%) (16/56)	45.3% (6.8%) (24/53)	42.9% (6.6%) (24/56)	38.8% (3.8%) (64/165)
	\$6.00	10.2% (4.4%) (5/49)	3.9% (2.7%) (2/52)	10.4% (4.5%) (5/48)	8.1% (2.2%) (12/149)
I (Ia & Ib) ($p = 0.5$)	\$1.00	35.6% (5.2%) (31/87)	40.0% (5.5%) (32/80)	42.9% (6.6%) (24/56)	39.0% (3.3%) (87/223)
	\$6.00	11.0% (3.7%) (8/73)	5.4% (2.6%) (4/74)	10.4% (4.5%) (5/48)	8.7% (2.0%) (17/195)
II ($p = 0.75$)	\$2.30	21.4% (1.4%) (3/14)	13.3% (9.1%) (2/15)		17.2% (7.1%) (5/29)
	\$3.90	9.8% (4.7%) (4/41)	5.7% (4.0%) (2/35)		7.9% (3.1%) (6/76)
III ($p = 0.5$)	\$2.80	7.7% (5.3%) (2/26)	3.1% (3.1%) (1/32)		5.2% (2.9%) (3/58)
	\$4.20	5.9% (4.1%) (2/34)	7.1% (5.0%) (2/28)		6.5% (3.1%) (4/62)
IV ($p = 0.25$)	\$2.40	12.2% (5.2%) (5/41)	11.4% (4.8%) (5/44)		11.8% (3.5%) (10/85)
	\$6.80	5.3% (5.3%) (1/19)	0.0% (0.0%) (0/16)		2.9% (2.9%) (1/35)

Notes: The second line in each panel contains standard errors for the strike probabilities in the first line; the third line gives these probabilities as strikes/trials. The table excludes two cases in which an informed (but confused) player gave up more than the small pie even though the small pie was drawn.

TABLE 3—INCIDENCE OF STRIKES IN RANDOM-DICTATOR GAMES

Game	Pie size	Session 1	Session 2	All sessions
I ($p = 0.5$)	\$1.00	39.6% (7.1%) (19/48)	41.2% (6.0%) (28/68)	40.5% (4.6%) (47/116)
	\$6.00	0.0% (0/72)	0.0% (0/52)	0.0% (0/124)
II ($p = 0.75$)	\$2.30	17.6% (6.5%) (6/34)	27.3% (9.5%) (6/22)	21.4% (5.5%) (12/56)
	\$3.90	0.0% (0/76)	0.0% (0/78)	0.0% (0/154)
III ($p = 0.5$)	\$2.80	6.6% (3.2%) (4/61)	15.9% (5.5%) (7/44)	10.5% (3.0%) (11/105)
	\$4.20	0.0% (0/48)	0.0% (0/56)	0.0% (0/104)
IV ($p = 0.25$)	\$2.40	8.8% (3.4%) (6/68)	12.5% (3.7%) (10/80)	10.8% (2.6%) (16/148)
	\$6.80	0.0% (0/32)	0.0% (0/18)	0.0% (0/50)

Note: The second line in each panel referring to the bad pie contains standard errors for the strike probabilities in the first line; the third line gives these probabilities as (strikes/trials). The table excludes three cases in which an informed player gave up more than the small pie even though the small pie was drawn.

we will summarize our data on messages and proposals, with particular attention to possible violations of inscrutability.

Tables 2 and 3 show the incidence of strikes in the bargaining and RD experiments.⁶ It is apparent that the incentive-efficiency prediction does not work perfectly. In the bargaining experiment, strikes sometimes occurred even though the good pie was drawn, and in both experiments

strikes also occurred in the bad states of games III and IV, contrary to the efficiency prediction. These inefficient strikes would reject a strict version of the efficiency prediction, but such a rejection would be too harsh. In fact, there is generally a nonnegligible incidence of strikes in complete-information experiments, in which strikes cannot be construed as efficient.⁷ Our conclusion is

⁶We report results by session and also pooled over all sessions. To justify pooling, we tested and failed to reject the hypothesis that strike incidence was constant across sessions within each game. We also tested and failed to reject the hypothesis that our data were consistent with Nash equilibrium play. We did this by testing whether the IC constraints (1) were violated by the average player in each game (i.e., whether the informed player could gain by using the big-pie strategy when the pie was in fact small and vice versa).

⁷A review of complete-information bargaining experiments indicates that the incidence of apparently inefficient strikes in our experiments is not atypical. The following rough summary shows the range of strike-incidence results across the various treatments in each study (where a "strike" means failure to reach a Pareto optimum): 0–37% (Malouf and Roth, 1981); 5–35% (Janet Neelin et al., 1988); 8–33% (Roth and Murnighan, 1982); 10–29% (Jack Ochs and Roth, 1989); 10–29% (W. Guth et al., 1982); 19–42% (Binmore et al., 1985); 19–67% (Forsythe et al., 1990).

that the efficiency principle is successful in explaining the main fluctuations in strike incidence across games in our experiments: in both experiments, strike incidence was significantly higher when the small pie was drawn in games I and II.

Given that the good pie was drawn, the average strike incidence in the bargaining experiment was 7.6 percent, and the variation across games was not statistically significant. Adding in the bad states of games III and IV (to cover all cases in which efficient strikes are ruled out), the overall incidence was 8.0 percent (41 strikes in 511 trials), with no significant variation between cases. In the RD experiment, strikes never occurred in the good state, since no player ever demanded more than the good pie. However, when the bad pie was drawn, the incidence of strikes in each game was essentially the same as in the corresponding bargaining game.

Although incentive efficiency explains why strike incidence was high in the bad states of games I and II, it leaves substantial unexplained variation between these two games. In both the bargaining and the RD experiments, incidence in the bad state was significantly higher in games I and II than in games III and IV, but incidence was also significantly higher in game I than in game II. Notice that the informed player in game II could afford to concede half of the good pie (\$1.95) even if the bad pie (\$2.30) was actually drawn, while in game I the informed player could not afford to do this. In fact, we chose the parameters of games II and IV after observing the results of games I and III in the bargaining experiment, with the idea that strike incidence might be affected by whether the informed player could always afford to concede half of the good pie. This kind of concession was never made in the bargaining experiment, and in any case such concessions make no sense in the RD experiment, in which the results of games I and II were also significantly different. Appendix B shows the gap between the parties' best offers for each strike in the bargaining experiment. In many cases, the informed player was offering less than the small pie, while the uninformed player ei-

ther had made no offer or was demanding more than the small pie. Note, however, that all of the uninformed players' demands in games II and III could have been met, regardless of the state. In contrast, the informed players often could not afford to meet the uninformed players' demands in the bad state in games I and IV.

An alternative and more promising line of inquiry follows from the observation that the strike frequencies are remarkably similar across the bargaining and RD games. In the RD games, the unexplained variation in strike incidence can only be due to the misspecification of players' objectives. Suppose for example that some players were mildly altruistic or risk-averse. Such players might take \$1.15 for sure in game II, leaving \$1.15 or \$2.75 for the other player, while refusing to take \$0.50 in game I. This is discussed further in Section V below.

In summary, we have shown that the existence of unverifiable private information in a bargaining game may cause strikes even though free communication is allowed between the bargainers. We have also found support for the view that strikes are an efficient response to incentive-compatibility constraints, in the sense that strikes are much less likely to occur in situations where incentive-efficient strikes are not possible. In the next section, we will summarize the proposals and final agreements in the experiments and discuss evidence suggesting that at least some subjects were not selfish expected-income maximizers.

IV. Comparison of the Bargaining and Random-Dictator Games

We have shown that incentive efficiency gives a useful explanation of the strike-incidence results but that some anomalies remain. We now consider alternative explanations for the anomalies, concentrating on the question of why strike incidence was much higher in game I than in game II.

Table 4 summarizes the strike incidence results in Tables 2 and 3, showing the percentage of the pie that was lost in relation to how the pie was divided between the players (the columns labeled U and I show

Note: There are minor inconsistencies across the columns of this table, because of rounding error.

the mean payoffs for the uninformed and informed players, counting strikes as zero payoffs). The table also shows the prediction of the RD axiom for each game. In the bargaining experiment, the uninformed player always did at least as well as the informed player in the bad state, while the informed player did better in the good state.

In the RD experiment, the informed player always did better than the uninformed player, regardless of pie size. In both experiments, the average value of the game was higher for the informed player. The percentage of the pie lost in the RD experiment was lower, on average, than in the corresponding games in the bargaining ex-

Note: The Wilcoxon signed-ranks statistic D is the sum of the ranks of the random-dictator observations. If N_1 is the number of observations in the bargaining game and N_2 is the number of observations with the random-dictator game, the T value we report is⁵

$$T = (D - N_1 N_2 / 2) / [(N_1 N_2 (N_1 + N_2 + 1) / 12)]^{1/2}$$

which is approximately a standard normal random variable for large values of N_1 and N_2 . This table excludes five cases in which the informed player gave up more than the small pie even though the small pie was drawn.

periment, mainly because strikes did not occur in the good state of the RD experiment.

The main difference in design between the two experiments is that the RD experiment suppresses the communication of messages and proposals; in addition, each player in the bargaining experiment had the right to reject any demand made by the other. On the face of it, suppressing communication makes a big difference, since there is an enormous variety of messages which could be sent, and it would be impossible to write down a complete strategy for the bargaining game, specifying the message to be sent after each possible history. From another point of view, the communication in the

bargaining experiment is merely cheap talk, since the informed player can send no message that credibly reveals that the pie is small, and if both players are selfish expected-income maximizers, this is the only piece of information that is relevant. This cheap-talk interpretation is based on stringent assumptions about preferences, however; what if some of the subjects find it difficult to lie? Moreover, even if the preference assumptions are valid, Joseph Farrell and Robert Gibbons (1989) have shown that cheap talk can support bargaining equilibria that would not otherwise be possible.

Our results show that the general pattern of the outcomes in the bargaining games was very similar to that of the RD games.

Communication did not substantially affect the incidence of strikes in the bad state; however, in the good state, strikes occurred only in the bargaining games, where the informed player could insist that the pie was small and the uninformed player had the right to insist that it was not. Moreover, Table 5 shows that, with the exception of game I, there were no statistically significant differences in pie splits between the two experiments. Furthermore, the unexplained variation in strike activity between games I and II occurred in both experiments, so the source of this variation apparently lies in the subjects' preferences, rather than in any messages that passed between them.

A. Altruism

In the bargaining games, violations of the inscrutability assumption might be interpreted as a concern for fairness, because revealing private information benefits both players collectively by reducing strikes. More generally, offering more than is necessary to get the other player to agree to one's demand would be evidence of altruism. If informed players behaved inscrutably in the bargaining games, then the conditional distribution of offers, given that the big pie is drawn, should be the same as the conditional distribution given the small pie. At the other extreme, if an informed player offers more than the small pie, the uninformed player can confidently infer that the big pie has been drawn, and the game transposes to one of complete information; we call this a "revealing offer."

Table 6 shows the frequency distributions of "best offers" made by the informed players, conditioned on whether the pie was big or small. The informed players behaved inscrutably in some, but not all, of these games. In game III, for instance, the conditional distributions are almost identical: the informed player usually offered half of the small pie (\$1.40) and sometimes offered a little more, regardless of whether the pie was in fact big or small. In game II, on the other hand, the informed player was much more likely to make a favorable offer in the

good state. Although the data are less clear, it seems reasonable to infer that inscrutability failed in games I and IV also.⁸

Revealing offers were made surprisingly often in game I, as can be seen in Table 6. In games II and III, a revealing offer requires that the informed player give up substantially more than half of the big pie; as one might expect, this never happened. In game IV, as in game I, the big pie (\$6.80) was more than twice the small pie (\$2.40), yet revealing offers were made in only 2 of 35 trials in game IV. A summary of revealing offers is given in Table 7. The chi-square tests shown there support the hypothesis that these offers were just as likely in the second experimental session as in the first.

We cannot conclude that violations of inscrutability result from players' concerns for fairness in the bargaining games, since we do not know the minimum offer necessary to achieve an agreement in these games. In the RD games, however, players could unilaterally impose the outcome. Thus, informed players could simply give their opponents nothing, and uninformed players should always take at least the small pie. Deviations from these strategies can only be due to altruism. In 18.6 percent (80/430) of the RD games, the informed player gave the uninformed player more than ten cents.⁹ This happened less often in session II (7.1 percent, or 15/210) than in session I (29.5 percent, or 65/220). In session I, 12.7 percent (28/220) of the uninformed players demanded less than the bad pie, and the corresponding figure in session II was 4.3 percent (9/210). We conclude that the typical player in these games behaved selfishly but that altruism, although not typical, had a substantial influence on the outcomes.

⁸Of course, each player saw only a fragment of Table 6, so that even in those games where inscrutability failed, the informed player's behavior might not convey much information to the uninformed player.

⁹Some informed players gave their opponents a penny (eight instances), a nickel (two instances), or a dime (17 instances). We prefer not to consider such trifling amounts as evidence of altruism.

B. Attitudes Toward Risk

Table 8 lists the demands of the uninformed players in each game of the RD experiment. Selfish and risk-neutral players would demand π_g in games I and II, and π_b in games III and IV. The typical player behaved this way in games I, III, and IV, but not in game II. The expected value of the tough demand in game II was \$2.93, but about half of the players instead chose \$2.30 as a sure thing. This might be due to mild risk aversion combined with some concern for fairness (since the tough demand leaves nothing for the informed player, while the weak demand leaves \$1.60 when the pie is big). The typical player in game I made the tough demand, but a substantial minority (18 percent) appeared to be strongly risk-averse, choosing \$1.00 for sure over a 50-percent chance of \$6.00. At the other ex-

treme, a substantial minority (21 percent) of the players in game IV appeared to be risk-seekers, choosing a 25-percent chance of getting (at most) \$6.80 over \$2.40 as a sure thing. We conclude that while the typical subject appeared to be risk-neutral, there were important deviations from this type in both directions.¹⁰

¹⁰If the subjects were all selfish expected-utility maximizers (and if this were common knowledge), the heterogeneity in risk attitudes could be eliminated by using the ingenious binary lottery procedure introduced by Roth and Malouf (1979). We chose not to use this procedure, mainly because it introduces considerable additional complexity in an already complicated experimental environment. In addition, the procedure works only under assumptions which are implausible in our context: that each subject acts selfishly and obeys the compound lottery axiom and that this is common knowledge.

C. Heterogeneity of Preferences

As Table 8 shows, the RD experiment uncovered considerable heterogeneity in subjects' preferences with regard to fairness and risk. This heterogeneity may help explain the variations in strike incidence in the bargaining experiment. In particular, although the uninformed player might maximize the expected payoff by playing tough in both games I and II, the expected loss from playing soft was less in game II, so that this option was more attractive to some risk-averse or altruistic players. On the other hand, although the soft strategy might maximize expected payoff in game IV, the tough strategy was apparently more attractive to a minority of risk-loving players. Since we have repeated observations on each individual, we can measure the extent to which atypical outcomes in each game are due to the presence of subjects with atypical preferences.¹¹

Table 9 shows individual effects on strike incidence. First consider the RD experiment, which directly measures heterogeneity. Table 9A shows the number of times each uninformed player proposed a strike (i.e., made a proposal that exceeded the small pie). In games I and II, a risk-neutral and selfish player should always make such a proposal, and in games III and IV, never. The results show that there are indeed some consistent differences in behavior across subjects. In game I, 16 of 24 players issued strike proposals in all five games in which they were uninformed, while only one of the 24 consistently chose to avoid a strike. A surprising result is that the other seven players in game I behaved inconsistently, sometimes choosing a strike proposal and sometimes not (these inconsistencies persisted in the second session, after the play-

ers had had plenty of time to learn the game). One might infer that these players were sufficiently altruistic or sufficiently risk-averse that they were indifferent between tough and soft proposals. By contrast with game I, only three of 20 players consistently chose to strike in game II, while nine of the 20 players behaved inconsistently. In games III and IV, only one player consistently chose to strike, and there was a slight majority of players who consistently played soft in each game.

In the bargaining games, the measurement of individual effects is less clear-cut, since the number of times each subject played against an informed player with a small pie was determined by chance. Table 9B shows the distribution of strikes over individuals, given that the small pie was drawn. Consistency of the outcomes in the bargaining games means either an entry in the first column (where the uninformed player is never involved in a strike) or else an entry on the main diagonal (where the uninformed player is involved in a strike every time the small pie is drawn). In game Ib, for instance, six of the 42 players were always involved in strikes, 15 were never involved, and the other 21 were sometimes involved in strikes. The small gap between strike probabilities in games II and IV, which was shown in Table 2, virtually disappears in Table 9: here 76 percent (13/17) of the uninformed players in game II were never involved in (small-pie) strikes, while the corresponding figure for game IV was 75 percent (18/24). On the other hand, the prevalence of strikes in game I stands out even more clearly here: only 30 percent (19/62) of the uninformed players were never involved in strikes.

Thus, it appears that there was a substantial degree of heterogeneity across players which blunted the incentive-efficiency prediction that strikes should occur only when the bad pie is drawn and when a risk-neutral and selfish player would rationally choose to play tough. However, a fair summary of the results is that the incentive-efficiency prediction works well when the expected payoff from being tough is large

¹¹A formal statistical analysis of individual effects would be possible, but only if the experiment were greatly enlarged. For example, we have only five measurements from which to infer the idiosyncratic behavior of each subject as an uninformed player, and these same measurements must also be used to draw inferences about the informed players on the other side.

TABLE 9—INDIVIDUAL STRIKE EFFECTS IN BARGAINING AND RANDOM-DICTATOR GAMES

Note: A strike means that the uninformed player demanded more than the small pie.

^aThe table excludes two players in game II, and two in game III, because they did not participate in all 10 periods.

enough (relative to the payoff from being soft) to overcome a mild dose of risk aversion or altruism.¹²

¹²One might reduce the problem of heterogeneity by conducting the experiment in two phases, using the first phase to screen out undesirable subjects; but if, for example, no two subjects are exactly alike in the extent to which they are altruistic, risk-averse, or consistent, the heterogeneity problem cannot be eliminated. Moreover, there are additional strategic complications in the screening phase of the game, since some players who should be screened out might dissemble if they desire to play the second phase of the game. This problem could be reduced by making the second phase

V. Conclusions

We have carried out an experiment designed to analyze the effect of one-sided private information on the outcomes of two-person bargaining games. The main question is whether "strikes" (failure to reach agreement) can be interpreted as efficient responses to the incentive constraints arising from private information. The bar-

attractive only to the subjects who are targeted for study, but the analysis of the entire game is likely to be very complicated.

gaining experiment allowed free exchange of messages between the two players, which makes the games more realistic, but which also means that a strategic analysis would be impossibly complicated. We therefore considered an abstract approximation of these games, in which the players are supposed to bargain over alternative mechanisms which might be used to divide the pie. For some parameter values, all mechanisms involving strikes are dominated, according to the criterion of incentive-efficiency, and thus strikes should not occur. Our experiment included two games of this kind, as well as two games in which efficient strikes could occur in the bad state.

The main conclusion is that the abstract principle of incentive-efficiency is very helpful in explaining the actual incidence of strikes in our experimental bargaining games. In general, strikes occurred much more often in the bad states of games I and II, where the condition for efficient strikes was satisfied, than in those situations where strikes were inefficient. Since our experiment was designed as a compromise between realistic bargaining games and Myerson's (1984) abstract model of bargaining over mechanisms, the results suggest that the incentive-efficiency principle may prove robust in applications.

The incentive-efficiency principle identifies circumstances in which strikes should not occur, but when efficient strikes are possible it does not predict how often they will actually happen. We used Myerson's random-dictator axiom to obtain more specific predictions, but these predictions performed poorly in some cases with regard to both the incidence of strikes and the division of the pie. The random-dictator axiom asserts that the outcome will be as if the two parties randomized equally between the mechanisms each would unilaterally impose, if given dictatorial power. This implies that strikes should occur 50 percent of the time in the bad states of games I and II; but in fact, strikes were much more frequent in game I than in game II.

We carried out another experiment designed to test the random-dictator axiom directly, with the idea that perhaps the fail-

ure of this axiom was due to the use of unconstrained "cheap talk" in our bargaining experiment. In fact, however, the random-dictator results were remarkably similar to those of the bargaining games. We concluded that the random-dictator axiom failed because there was considerable heterogeneity among our subjects, including sizeable minorities of both risk-averse and risk-loving types, and another minority of altruists.

Although we have some encouraging results on the predictive power of the incentive-efficiency principle, the results on heterogeneity of preferences and on inconsistency of decisions indicate that much caution is needed in drawing conclusions from behavior in bargaining (and other) experiments. In any game in which the players interact strategically, the theoretical analysis should not begin (as ours did) with the assumption that the players' objective functions are common knowledge. In addition, given that there is a nontrivial distribution of objective functions in the population of potential subjects, it is difficult to see how the actual subjects could know what this distribution is.

APPENDIX A

Instructions for Bargaining Game [Exact Transcript]

General

You have been asked to participate in an experiment, consisting of two sessions, in the economics of bargaining. If you follow these instructions carefully and make good decisions, you might earn a considerable amount of money, which will be paid to you in cash at the end of the second experimental session.

Each experimental session will consist of five separate bargaining periods lasting ten minutes each. In each of these periods you will be bargaining with a different person who is in another room. Once this ten minute period is over, you will never bargain with this person again. The individuals you bargain with in the first session are different from the individuals you bargain with in the second session. You will not be told who these people are either during or after the experiment. In each of these ten bargaining periods, you will negotiate with one of these persons to decide how to divide a sum of money.

You will notice that there are other people in the same room with you who are also participating in bargaining experiments. You will never be bargaining with any of these people during either bargaining ses-

sion. The decisions that they make will have absolutely no effect on you nor will any of your decisions affect them.

In each period, one bargainer will have more information than the other. In particular, the bargainer in one room will know the amount of money that is available to be bargained over for the period. The bargainer in the other room will only know that it is one of two possible amounts, \$6.80 or \$2.40. We will alternate which set of bargainers will be INFORMED and which will be UNINFORMED from one period to the next. In particular, if you are in room A you will be informed during all even numbered periods while if you are in room B you will be informed during all odd numbered periods. Thus, you will alternate between being an INFORMED bargainer and an UNINFORMED bargainer during the ten bargaining periods of the experiment.

The amount of money you will be bargaining over in a bargaining period will be determined at the start of each period. In each period, the \$2.40 amount is three times as likely to occur as the \$6.80 amount, regardless of what has happened previously. Before a bargaining period begins, each INFORMED bargainer will draw from a box containing one hundred poker chips. Seventy-five of the chips are white and correspond to the \$2.40 amount while the other twenty-five chips are blue and correspond to the \$6.80 amount. Thus, if a white chip is drawn, you will be bargaining over \$2.40 while if a blue chip is drawn you will be bargaining over \$6.80. At the beginning of each period, a separate, independent drawing will be held which determines the amount to be bargained over for that period. The amount to be bargained over in a given period will depend only on the color of the chip that is drawn for that particular period. In particular, a white chip is three times more likely to be drawn than a blue chip at the beginning of any period. The outcome of the drawing in any one period will have no effect on the outcome of the drawing in any other period.

A bargaining period will last for 10 minutes. During this time you will negotiate over how the money is to be divided. The bargaining will be over the amount the UNINFORMED bargainer is to receive. The amount of money that the INFORMED bargainer receives will be the actual amount of money at stake minus the amount that the UNINFORMED bargainer receives. Neither bargainer earns anything for the period unless an agreement is reached.

In your folder you will find two profit sheets—one for each session in which you will participate. Your “Beginning Cash Balance” is shown on the first row of your profit sheets. If this is your first session, this amount is \$10. If this is your second session, this is your cash balance from the end of the first session. The information next to each bargaining period number tells you whether you are the INFORMED or the UNINFORMED bargainer for that period. At the beginning of each period, the INFORMED bargainer should fill in the “Amount Bargained Over” for that period. Recall that this amount is determined by the color of the chip that the INFORMED bargainer draws from the box. If you and the other bargainer reach an agreement in a period, you should fill in the amount you receive on the row labeled “Your Earnings” for

that period. If you are the UNINFORMED bargainer, this is the amount you agreed to. If you are the INFORMED bargainer, this is the “Amount Bargained Over” minus the amount you agreed that the UNINFORMED bargainer should receive. If you and the other bargainer did not reach an agreement during the ten-minute bargaining period, you should record zero as your earnings for that period.

At the end of an experimental session, add “Your Earnings” from each of the five periods to your “Beginning Cash Balance” and record the total in the row corresponding to the “End of Session Cash Balance.” If this is the end of your first experimental session, this amount will be your “Beginning Cash Balance” when you begin the second session. If this is the end of your second experimental session, the experimenter will pay you this amount in cash.

Bargaining Rules

You will be able to bargain by sending messages and formal proposals to the other bargainer. On your table you will find an ample supply of a form labeled “Message Form.” You must fill in the number of the other bargainer and the bargaining period on this form. In your messages, you may communicate whatever you wish, except that you cannot make physical threats or reveal your identity. If you wish to send a message simply hand it to the experimenter who will deliver it for you, unless there is a message from the other bargainer about to be delivered to you. (That is, messages will not be allowed to cross in the mail.)

If you wish to make a formal proposal fill in an amount on the bottom line of your message form where it states: “I propose that the uninformed bargainer receive.” Once you have made a formal proposal, the other bargainer can accept it at any time; you can not take it back. If you wish to accept a proposal which has been made by the other bargainer, you must check the space marked “accept” on this proposal form and hand it to the experimenter.

You may send as many messages as you wish. You may also send as many formal proposals as you wish but remember that sending a new proposal does not cancel any of your previous proposals. You may have as many formal proposals outstanding during a bargaining period as you wish. The person you are bargaining with is free to accept at most one of these proposals. Similarly, you may receive many formal proposals from the person you are bargaining with and you may accept at most one of these proposals.

If you accept a formal proposal that was made by the other bargainer or if the other bargainer accepts a proposal which you made, this acceptance constitutes a binding contract and determines your earnings for that period. If no proposal has been accepted when the buzzer sounds to indicate the end of the period, neither bargainer receives anything for that period.

If you accept a proposal during a bargaining period, you should record your earnings from the agreement on your Profit Sheet at that time and wait for the next bargaining period to begin. You will need to change this amount only if the other bargainer accepts one of your proposals first. If no proposal is accepted in a bargaining period before the time limit is exceeded,

you should record "0" as your earnings on your Profit Sheet.

You will keep track of the time remaining in any period yourself, using the clock in your room or your own watch. When you receive a message, there will be a number in the upper right hand corner of the message form. This indicates the amount of time left in the current bargaining period. We will only tell you when a period is starting and when it is ending. We ask that you do not talk to other bargainers in your room until your bargaining session is completed. Do not be concerned if other bargainers finish a particular bargaining period before you complete it. A new period will not begin until all bargainers have completed bargaining for the current period.

In summary, your earnings in the experiment will be the total of your beginning cash balance plus your share of any agreements reached during the experiment. The amount of money you earn will depend partly upon luck and partly upon whether you have made good decisions. Your earnings will be exactly what you agreed to in the course of bargaining, as indicated on your profit sheets. Are there any questions?

Instructions for Random-Dictator Game
[Exact Transcript]

General

You have been asked to participate in an economics experiment consisting of two sessions. If you follow these instructions carefully and make good decisions, you might earn a considerable amount of money, which will be paid to you in cash at the end of the second experimental session.

Each experimental session will consist of five separate periods. In each of these periods you will be paired with a different person who is in another room. Once this period is over, you will never be paired with this person again. The individuals you are paired with in the first session are different from the individuals you are paired with in the second session. You will not be told who these people are either during or after the experiment. In each of these ten periods, you will be paired with one of these persons to decide how to divide a sum of money.

You will notice that there are other people in the same room with you who are also participating in the experiment. You will never be paired with any of these people during either session. The decisions that they make will have absolutely no effect on you nor will any of your decisions affect them.

In each period, one person in each pair will have more information than the other. In particular, the person in one room will know the amount of money that is available for the period. The person in the other room will only know that it is one of two possible amounts, \$6.00 or \$1.00. We will alternate which set of people will be INFORMED and which will be UNINFORMED from one period to the next. In particular, if you are in room A you will be informed during all even numbered periods while if you are in room B you will be informed during all odd numbered periods. Thus, you will alternate between being INFORMED

and UNINFORMED during the ten periods of the experiment.

Determining the Amount Of Money Available in Each Period

The amount of money available to be divided between each pair will be determined at the start of each period. In each period, the \$1.00 amount is just as likely to occur as the \$6.00 amount, regardless of what has happened previously. Before a period begins, each INFORMED person will draw a chip from a box labeled "MONEY BOX." This box contains one hundred poker chips. Fifty of the chips are white and correspond to the \$1.00 amount while the other fifty chips are blue and correspond to the \$6.00 amount. Thus, if a white chip is drawn the amount available will be \$1.00 while if a blue chip is drawn the amount available will be \$6.00. At the beginning of each period, a separate, independent drawing will be held which determines the amount available for that period. The amount available in a given period will depend only on the color of the chip that is drawn for that particular period. In particular, a white chip is just as likely to be drawn as a blue chip at the beginning of any period. The outcome of the drawing in any one period will have no effect on the outcome of the drawing in any other period.

Determining the Amount Each Person Receives

In a period you must propose how the money is to be divided. Each person will have to make a proposal which specifies the amount the UNINFORMED person is to receive. To do this, you must submit a proposal on a "Proposal Form." You will find an ample supply of these forms on the table in front of you. You must fill in the period number and the number of the other person you are paired with on this form. Once you have come to a decision about how much you wish to propose that the UNINFORMED person should receive, simply write that amount on a proposal form and hand it to the experimenter.

After all people have submitted their proposals, the UNINFORMED person will draw a chip from a box labeled "Proposal Box". This box contains one hundred chips. Fifty of the chips are red while the other fifty of the chips are white. The color of the chip which is drawn will determine whether the INFORMED person's proposal or the UNINFORMED person's proposal is used. If a red chip is drawn, then the UNINFORMED person's proposal will be used, while if a white chip is drawn then the INFORMED person's proposal will be used. Remember that the box contains an equal number of white chips and red chips, so that each person's proposal will have an equal chance of being selected.

The amount of money which each person receives is determined as follows:

- 1) If the selected proposal specifies that the UNINFORMED person should receive more than the amount of money available, neither person will earn anything for the period.
- 2) If the selected proposal specifies that the UNINFORMED person should receive an amount which

does not exceed the amount of money available, then the UNINFORMED person will receive the amount of money specified in the proposal. The INFORMED person will receive the amount of money which is left over.

Do not be concerned if other people finish a particular period before you complete it. A new period will not begin until all people have completed the current period.

If you have any questions during the experiment, ask the monitor in your room and he or she will answer them for you. Other than these questions, you *MUST* keep silent until your session is completed. If you break this silence while the experiment is in progress, you will be given one warning. If you continue to talk after you have been warned, you will be asked to leave the experiment and YOU WILL FORFEIT YOUR EARNINGS.

Recording Rules

In your folder you will find an information sheet. Your "Beginning Cash Balance" of \$10 is shown on the first row of your profit sheet. The information next to each period number tells you whether you are the INFORMED or the UNINFORMED person for that period. It also tells you the number of the person you are paired with for the period. During those periods in which you are the INFORMED person you should fill in the "Amount of Money Available" for that period. Recall that this amount is determined by the color of the chip that the INFORMED person draws from the "Money Box." During those periods in which you are the UNINFORMED person you should circle whether the informed person's proposal or the uninformed person's proposal has been selected. Recall that the proposal that will be used is determined by the color of

the chip that the UNINFORMED person draws from the "Proposal Box."

At the end of a period, we will give you a copy of your profit sheet for the period. We have included a blank profit sheet in your folder which you should look at now. On this sheet we will have recorded the amount of your proposal on the line labeled "Your Proposal." We will also have recorded the other person's proposal on the line labeled "Other Proposal." The proposal which we have circled is the one that will be used in this period. Finally, we have recorded your profits for the period on the line labeled "You Receive." Recall that this amount will be zero if the selected proposal exceeds the amount of money available. Otherwise, this is the amount specified on the selected proposal if you are the UNINFORMED person. If you are the INFORMED person, this is the "amount of money available" minus the amount that the UNINFORMED person receives. You should record your profits for the period on your information sheet.

At the end of an experimental session, add the amount you have received from each of the five periods to your "Beginning Cash Balance" and record the total in the row corresponding to the "End of Session Cash Balance." If this is the end of your first experimental session, this amount will be your "Beginning Cash Balance" when you begin the second session. If this is the end of your second experimental session, the experimenter will pay you this amount in cash.

In summary, your earnings in the experiment will be the total of your beginning cash balance plus the amount you earn during each period of the experiment. The amount of money you earn will depend partly upon luck and partly upon whether you have made good decisions. Your earnings will be exactly what is indicated on your profit sheets. Are there any questions?

On the Sign of the Investment–Uncertainty Relationship

By RICARDO J. CABALLERO*

Understanding the effects of uncertainty over any decision variable has fascinated economists for a long time. Risk aversion and incomplete markets are likely to make the investment–uncertainty relationship negative (e.g., Roger Craine, 1989; Joseph Zeira, 1989). What happens in the absence of risk aversion and incomplete markets is, however, ambiguous.

Richard Hartman (1972) and Andrew B. Abel (1983, 1984, 1985) found that in the presence of (symmetric) convex costs of adjustment, mean-preserving increases in price uncertainty raise investment of a competitive firm as long as the profit function is convex in prices. On the other hand, the recent literature on irreversible investment (e.g., Robert S. Pindyck, 1988; Giuseppe Bertola, 1988) has shown that increases in uncertainty lower investment. All these results have been derived under either risk neutrality or complete markets.¹

Intuition suggests that the explanation for such a difference lies with the asymmetric nature of adjustment costs in the irreversible-investment case, as compared with the symmetry of the adjustment-cost mechanisms proposed by Abel and Hartman. Although this intuition is confirmed in this paper, asymmetric adjustment costs are

shown not to be sufficient to explain why the results differ. In fact, a more hidden but at least as important difference between these two literatures is that the former assumes perfect competition and constant returns to scale, whereas the latter assumes either imperfect competition or decreasing returns to scale (or both).²

The purpose of this paper is to highlight the role of the decreasing marginal return to capital assumption (due to either imperfect competition or decreasing returns to scale [or both]) in determining the effects of adjustment-cost asymmetries on the sign of the response of investment to changes in uncertainty (under risk neutrality). For this, the paper develops a simple model with a cost-of-adjustment mechanism general enough to consider both symmetric-convexity and irreversibility as special cases. One of the most important findings is the lack of robustness of the negative relationship between investment and uncertainty under asymmetric adjustment costs³ to changes in the degree of competition. In fact, when firms are nearly competitive, the conclusion of Hartman and of Abel holds no matter how asymmetric adjustment costs are. Studying adjustment-cost mechanisms has a central role in understanding the dynamics of investment and its business-cycle implications, but conclusive results about the sign of the instantaneous relationship between uncertainty and investment should not be

*Department of Economics, Columbia University, New York, NY 10027. I am grateful to Giuseppe Bertola, Prajit Dutta, Glen Hubbard, Anil Kashyap, Richard Lyons, and the referees for their useful comments.

¹The financial literature on investment has considered risk aversion through a premium in the discount rate determined by the CAPM, (capital asset pricing model), intertemporal CAPM, or consumption CAPM. However, often this discount rate is left unchanged when studying the response of investment to uncertainty changes (e.g., Pindyck, 1988 pp. 974–5), thereby omitting the effect of changes in uncertainty on investment due to risk aversion (and incomplete markets).

²In the typical version of the irreversible-investment problem, there is no cost of upward adjustments; thus, imperfect competition and (or) decreasing returns to scale are required to bound the size of the firm.

³In this paper, *asymmetric* adjustment cost refers to the case in which it is more expensive to adjust downward than upward. Certainly, the opposite case is a trivial extension of the case studied in this paper.

expected from the adjustment-costs literature alone.

Section I develops the minimum framework necessary to understand the main issues involved. For this, a simple partial-equilibrium two-period model in which adjustment costs are (weakly) convex and possibly asymmetric and in which managers (owners) are risk-neutral is derived. Section II specializes the previous model to perfect competition. The result of Hartman and of Abel is shown to be robust to asymmetries in the adjustment-costs function, including the irreversible investment case. Hence, investment and uncertainty are positively correlated even in the extreme case of irreversible investment, as long as the firm faces a very elastic demand curve (and returns to scale are nondecreasing). Section III confirms the fact that the combination of important degrees of imperfect competition and adjustment-costs asymmetry may reverse the positive correlation between uncertainty and investment. In obtaining this result, imperfect competition is not only necessary, but is also the paramount factor. Section IV summarizes the results and discusses the roles of increasing and decreasing returns to scale. The latter makes a negative investment-uncertainty relationship more likely, whereas increasing returns makes it less likely. Finally, the Appendix presents an infinite-horizon version of the perfect-competition-adjustment-costs model.

I. Basic Framework

Each firm is in place for two periods⁴ and faces an isoelastic demand function:

$$(1) \quad P_t = Q_t^{(1-\psi)/\psi} Z_t$$

where ψ ($\psi \geq 1$) is a markup coefficient that takes the value of 1 under perfect competition, P and Q are respectively the price and quantity of the good sold, and Z is a stochastic term described by a lognormal

random-walk process:⁵

$$Z_t = Z_{t-1} \exp \varepsilon_t$$

with ε distributed normally with mean $-\sigma^2/2$ and variance σ^2 .

Technology is described by a homogeneous Cobb-Douglas production function:

$$Q = (AL^\alpha K^{1-\alpha})^\gamma$$

with A a scale parameter, L labor, K capital, α the labor share, and γ a returns-to-scale parameter.

Under these conditions the profit function, $\Pi(K, Z)$, is equal to

$$\Pi(K_t, Z_t) = h Z_t^\eta K_t^\mu$$

where

$$h = (1 - \alpha\gamma/\psi) A^{(\gamma/\psi)/(1-\alpha\gamma/\psi)}$$

$$\times \left(\frac{\alpha\gamma}{\psi w} \right)^{(\alpha\gamma/\psi)/(1-\alpha\gamma/\psi)}$$

$$\eta \equiv \frac{1}{1 - \alpha\gamma/\psi} > 1$$

$$\mu \equiv \frac{(1 - \alpha)\gamma/\psi}{1 - \alpha\gamma/\psi} \leq 1$$

and w is the (constant) wage paid to labor.⁶

Letting $C(I)$ denote the cost of changing the stock of capital by I units and assuming (without loss of generality) neither depreci-

⁵Assuming a stationary process instead of a (log) random walk does not change the conclusions.

⁶Note that the unambiguous convexity of $\Pi(\cdot, \cdot)$ with respect to Z depends on the fact that, given Q , the relation between P and Z depends on neither technology nor preference parameters. If, for example, (1) were replaced by $Q = P^{\psi/(1-\psi)} Z$, the profit function would no longer be convex with respect to Z . However, the specification in (1) seems more appropriate since it permits analysis of perfect competition as the limit case when $\psi = 1$, without altering the variance of the fundamental source of uncertainty, Z . In fact, when $\psi = 1$, (1) corresponds to the specification of Hartman and of Abel.

⁴See the Appendix for a multiperiod version of the perfect-competition version of the model.

ation nor discounting yields the following two-period optimization problem for a single firm:

$$(2) \quad V_1(K_0, Z_1) = \max_{I_1} \Pi(K_1, Z_1) - C(I_1) \\ + E_1[V_2(K_1, Z_2)] \\ \text{subject to } K_1 = K_0 + I_1$$

where V_i represents the value function at time i .

The first-order condition of this problem is

$$(3) \quad \Pi_{K_1}(K_0 + I_1, Z_1) - C_I(I_1) \\ + E_1[V_{2K_1}(K_0 + I_1, Z_2)] = 0.$$

Finally, the second-period (terminal) value function is just

$$(4) \quad V_2(K_1, Z_2) = \max_{I_2} \Pi(K_1 + I_2, Z_2) \\ - C(I_2).$$

The remainder of this section presents a general investment-cost function, while the rest of the paper discusses the role of competition, returns to scale, and the shape of the investment-cost function in determining the investment-uncertainty relationship.

The cost of changing the stock of capital by I units, denoted by $C(I)$, includes both direct and adjustment costs:

$$C(I) = I + [I > 0]\gamma_1 I^\beta + [I < 0]\gamma_2 |I|^\beta$$

where $\beta \geq 1$, γ_1 and γ_2 are two nonnegative parameters, and the price of capital has been set equal to 1.⁷

This parameterization of $C(I)$ is quite general. For example, except for the addition of I to reflect the direct cost of capital, the symmetric adjustment-cost case used by Abel (1983) is achieved when $\gamma_1 = \gamma_2 > 0$ and $\beta > 1$, and the irreversible-investment

case of Pindyck (1988) and Bertola (1988) corresponds to the case in which $\gamma_1 = 0$, $\gamma_2 = \infty$, and $\beta = 1$.

II. Perfect Competition

In order to isolate the role of competition, I will postpone issues of returns to scale until Section IV. For now, the technology is assumed to exhibit homogeneity of degree one with respect to capital and labor ($\gamma = 1$).

Moreover, perfect competition is taken only as an expository device to illustrate the consequences of a highly elastic demand. Indeed, Pindyck (1990) provides compelling arguments against mean-preserving changes in price-uncertainty experiments when competition is strictly perfect and investment is fully irreversible.

When competition is perfect $\mu = 1$; hence, the profit function becomes linear with respect to the stock of capital. This yields a simple first-order condition at time 2 [see eq. (4)]:

$$hZ_2^\eta - [I_2 > 0](1 + \gamma_1 \beta I_2^{\beta-1}) \\ - [I_2 < 0](1 - \gamma_2 \beta |I_2|^{\beta-1}) = 0.$$

Thus, I_2 is determined by

$$I_2 = \begin{cases} \left[\frac{hZ_2^\eta - 1}{\gamma_1 \beta} \right]^{1/(\beta-1)} & \text{for } I_2 > 0 \text{ or } hZ_2^\eta \geq 1 \\ - \left[\frac{1 - hZ_2^\eta}{\gamma_2 \beta} \right]^{1/(\beta-1)} & \text{for } I_2 < 0 \text{ or } hZ_2^\eta < 1. \end{cases}$$

The most important feature of this solution is that it does not depend on K_1 ; hence, the value function at time 2 is only linearly linked to K_1 through the profit function. It is easy to show that in this case $V_{2K_1} = hZ_2^\eta$.⁸

⁸The fact that $V_{2K_1} = hZ_2^\eta$ can be easily proved by noticing that I_2 does not depend on the stock of capital at time 1; therefore, $V_{2K_1} = \Pi_{K_1}(K_2, Z_2)$. Given that $\Pi(K_2, Z_2) = hZ_2^\eta K_2$ and $K_2 = K_1 + I_2$, then $V_{2K_1} = hZ_2^\eta$.

⁷Relaxing this assumption is trivial.

Plugging the expressions for $V_{2K_1}(\cdot, \cdot)$, $\Pi_K(\cdot, \cdot)$, and $C_I(\cdot)$ into equation (3) provides the first-order condition for the perfectly competitive, constant-returns-to-scale firm (at time 1):

$$\begin{aligned} & hZ_1^\eta(1 + e^{[\eta(\eta-1)/2]\sigma^2}) \\ & - [I_1 > 0](1 + \gamma_1\beta I_1^{\beta-1}) \\ & - [I_1 < 0](1 - \gamma_2\beta |I_1|^{\beta-1}) = 0 \end{aligned}$$

which yields the following investment function at time 1:

$$I_1 = \begin{cases} \left[\frac{hZ_1^\eta(1 + e^{[\eta(\eta-1)/2]\sigma^2}) - 1}{\gamma_1\beta} \right]^{1/(\beta-1)} & \text{for } I_1 > 0 \text{ or } hZ_1^\eta(1 + e^{[\eta(\eta-1)/2]\sigma^2}) \geq 1 \\ - \left[\frac{1 - hZ_1^\eta(1 + e^{[\eta(\eta-1)/2]\sigma^2})}{\gamma_2\beta} \right]^{1/(\beta-1)} & \text{for } I_1 < 0 \text{ or } hZ_1^\eta(1 + e^{[\eta(\eta-1)/2]\sigma^2}) < 1. \end{cases}$$

Again, investment at time 1 does not depend on either past or future capital stocks. This lack of "intertemporal links" does not depend on the two-period assumption. In fact, this insight also holds for the n -period model (see Appendix) and is crucial in determining the irrelevance of the shape (besides convexity) of the investment-cost function, under partial equilibrium and risk neutrality, vis-à-vis the response of investment to changes in the level of uncertainty.

The asymmetry of adjustment costs has nothing to do with the sign of the response of investment to increases in uncertainty. Whether investment is positive or negative depends on the sign of the numerator, and this does not include the adjustment-cost parameters. An increase in uncertainty raises investment (or reduces disinvestment) for any (finite) level of adjustment costs. The asymmetry determines only that investment and disinvestment have different speeds of adjustment. This is fully consistent with Hartman's (1972) and Abel's (1983,

1984, 1985) conclusion for the symmetric case. Notice that this is true even for the case in which β is very close to 1, γ_1 is slightly greater than 0, and γ_2 is ∞ , that is, when investment is irreversible and there are almost no costs (besides the price itself) of adjusting the capital stock upward.⁹

In sum, the fact that asymmetric costs imply a larger disequilibrium (as compared to the frictionless capital stock) when demand realizations are low, does *not* affect the conclusion that, under constant returns to scale and perfect competition (as well as risk neutrality and partial equilibrium), increases in uncertainty raise investment. This is just a reflection of the fact that, under perfect competition, how much is invested today affects profits tomorrow, but not the level of investment tomorrow. Therefore, any increase in the expected marginal profitability of capital, including the one caused by an increase in price uncertainty, raises investment today.

The next section relaxes the perfect-competition assumption to show that the interaction between decreasing marginal profitability of capital, resulting from imperfect competition (or decreasing returns to scale), and asymmetric costs can generate a negative investment-uncertainty relationship. In determining this relationship, imperfect competition not only is necessary but also plays a central role.

III. Imperfect Competition

When competition is imperfect there is, in general, no closed-form solution for the investment function (even in the simple two-period context).¹⁰ The exceptions correspond to extreme assumptions about $(\gamma_1, \gamma_2, \beta)$: no adjustment costs $(0, 0, \beta)$, irreversible investment with no (adjustment) cost of increasing the stock of capital $(0, \infty, 1)$, capacity constraints with no cost of

⁹It is well known that, under perfect competition and constant returns to scale, the size of the firm is indeterminate; therefore, some convexity in (upward) adjustment costs ($\gamma_1 > 0, \beta > 1$) is required in order to bound (positive) investment.

¹⁰At least, there is none known to me.

scrapping capital $(\infty, 0, 1)$, and predetermined capital (∞, ∞, β) . Here, I solve numerically several examples of the general $(\gamma_1, \gamma_2, \beta)$ case.

To streamline the notation, it is convenient to assume (without loss of generality) that $Z_1 \equiv 1$. It is also simpler (again, without loss of generality) to assume that there is no initial capital, with the result that I_1 is always positive. With these assumptions, I_1 and I_2 are determined by the following two equations:

$$\mu h I_1^{\mu-1} - \gamma_1 \beta I_1^{\beta-1} + \beta E_1([I > 0] \gamma_1 I_2^{\beta-1} - [I < 0] \gamma_2 |I_2|^{\beta-1}) = 0$$

$$\mu h Z_2^\eta (I_1 + I_2)^{\mu-1} - \beta \{ [I > 0] \gamma_1 I_2^{\beta-1} - [I < 0] \gamma_2 |I_2|^{\beta-1} \} = 0$$

corresponding to the first-order conditions in periods 1 and 2, respectively.

The problem is even further simplified by replacing the assumption of a lognormal distribution for Z with a simple symmetric Bernoulli distribution.¹¹ Figure 1 illustrates the independent (of asymmetries) role of imperfect competition in generating the negative investment-uncertainty relationship.¹² In this figure, adjustment costs are entirely symmetric; however the Jensen's inequality argument of Hartman (1972) and Abel (1983, 1984, 1985) becomes less significant as competition becomes more imper-

fect (ψ gets larger).¹³ The figure shows that as ψ increases (i.e., as the elasticity of demand is reduced), investment responds less and less to changes in the level of uncertainty.¹⁴ In fact, when $\psi > 1.6$, the lines characterizing the investment-uncertainty trade-off in Figure 1 are almost horizontal, indicating practically no effects of changes in the level of uncertainty on investment decisions. Again, it should be remembered that this has been achieved under perfectly symmetric adjustment costs.

There are two channels for the dampening of the result of Hartman and of Abel under imperfect competition (and symmetric adjustment costs). First, as the elasticity of demand is reduced, the convexity of the marginal profitability of capital with respect to price uncertainty, η , is reduced (given the stock of capital).¹⁵ This can be seen more clearly by using perfect competition as a benchmark. Recall that under perfect competition $P_t = Z_t$; hence, an increase in Z_t raises revenues both directly (through $Q\Delta P$) and indirectly through the increase in optimal output (given the stock of capital). The latter effect is responsible for the convexity of the profit function with respect to Z_t . When the elasticity of demand is less than infinite, however, the indirect effect is less important, as the firm's desire to increase output is less than that under perfect competition since doing it brings the price of its goods down, lowering the direct effect of a positive change in Z . Thus, as the elasticity of demand falls, the profit function becomes less convex with respect to Z_t . Second, as the markup (ψ) rises, the marginal profitability of capital (Π_K) decreases more with a given increase in capital (i.e., $\Pi_{KK\psi} < 0$).¹⁶ This, again, dampens the response of investment to an increase in

¹¹The interesting symmetric Bernoulli case is that in which the positive shock leads to positive investment in period 2 and a negative shock leads to disinvestment. The numerical problem is then trivial, as it consists of three equations (the expected value equation [first equation] and the two equations for the second period: one for the good realization and one for the bad realization) and three unknowns (investment in the first period and investment in the second period for the good and bad realizations). Certainly, generalizing this to any discrete-state space is trivial.

¹²All the curves (in all diagrams) are normalized by their respective level of investment under certainty.

¹³Notice that the level of adjustment costs is not important, since investment is normalized by the level of investment under certainty.

¹⁴Remember that $\psi = 1$ corresponds to the perfect competition case, whereas $\psi > 1$ represents imperfect competition (or decreasing returns to scale).

¹⁵Remember that η is decreasing in ψ .

¹⁶Remember that under perfect competition $\Pi_{KK} = 0$.

FIGURE 1. INVESTMENT AS A FUNCTION OF UNCERTAINTY FOR DIFFERENT VALUES OF ψ

price (demand) uncertainty, as the initial lift of the second period's expected marginal profitability of capital (due to Jensen's inequality) is curtailed by an increase in investment today. Combined, these two effects demonstrate that the result of Hartman and of Abel loses its strength under imperfect competition even when adjustment costs are symmetric.

Figure 2 shows the effects of asymmetric adjustment costs on the investment-uncertainty relationship, once competition is imperfect. The markup coefficient is 1.67 (this corresponds to an elasticity of demand equal to 2.5), and the cost of downward adjustments goes from being equal to the cost of upward adjustments of the capital stock (solid line), to being 50 times as expensive as the latter (short dashes). It is apparent that, given the presence of a significant degree of competition imperfection, the investment-uncertainty relationship becomes more negative as the adjustment-cost asymmetry gets larger.

Adjustment costs deform the relationship between realizations of the shock (innova-

tions), ε_2 , and the stock of capital at time 2 (when compared with the costless adjustment case). For example, if capital is predetermined (unchangeable both upward and downward), there is no link whatsoever between the realization of the shock and the stock of capital in the second period. In the irreversible-investment case, on the other hand, the capital stock and shocks are only linked for "good" realizations of the latter (i.e., for realizations in which the capital in place is less than the desired stock of capital). In general, for the asymmetric case, the stock of capital responds more to "good" than to "bad" realizations (i.e., realizations in which the capital in place is larger than the desired stock of capital). When competition is imperfect, the determination of what is a "good" and a "bad" shock is endogenous. It depends on how much is invested in the first period. The less the firm invests in the first period, the more likely it is to get a good shock (i.e., one in response to which the lowest adjustment cost is paid). Certainly, the cost of this strategy is less output today. When uncertainty is larger, "very

FIGURE 2. INVESTMENT AS A FUNCTION OF UNCERTAINTY FOR DIFFERENT DEGREES OF ASYMMETRY IN ADJUSTMENT COSTS ONCE COMPETITION IS IMPERFECT

good" and "very bad" news become more likely; but the larger the asymmetry of adjustment costs, the more expensive are the latter relative to the former. Thus, it is optimal to buy more protection, in the form of less initial investment, as the asymmetry and degree of uncertainty rise.

It is also worth noticing that the support of I_1 is larger in Figure 1 than in Figure 2, suggesting that imperfect competition (or decreasing returns to scale) not only is a necessary condition for asymmetric adjustment costs to affect the investment-uncertainty relationship, but also plays a central role.

IV. Conclusion

This paper has demonstrated that the presence of asymmetric adjustment costs is not sufficient to render a negative relationship between investment and mean-preserving changes in uncertainty. Some nonnegligible degree of imperfect competition is also required. In fact, the result of Hartman

(1972) and Abel (1983, 1984, 1985) (positive relationship between investment and uncertainty) for symmetric and convex adjustment costs under perfect competition fully carries over to the case of asymmetric adjustment costs. Furthermore, under very competitive conditions, the asymmetry of adjustment costs has little to do with the sign of the investment-uncertainty relationship. Today's investment decisions depend almost exclusively on the price of capital (today and in the future)¹⁷ and the expected marginal profitability of capital. In this case, the marginal profitability of capital is only tenuously related to the level of capital; hence, the convexity of marginal profitability of capital with respect to prices is the dominant factor in determining the sign of the investment-uncertainty relationship. A simple Jensen's inequality argument shows that the latter is positive.

¹⁷Assumed to be constant in this paper.

Conversely, when competition is imperfect, the marginal profitability of capital is significantly affected by the level of capital. An increase in investment today makes it more likely that the firm will find its second-period capital "too large" relative to the desired capital stock. When adjustment costs are asymmetric, having "too much" capital is worse than having "too little" of it, since increasing the stock of capital is cheaper than decreasing it. If this effect is sufficiently strong (i.e., the asymmetry of adjustment costs is large and the negative dependence of the marginal profitability of capital on the level of capital is strong), the investment-uncertainty relationship becomes negative. The irreversible-investment arguments analyzed in the literature typically correspond to this case.

Most of the analysis of this paper maintains the assumption of constant returns to scale. Relaxing this assumption, however, does not convey any additional difficulty. Convexity of the profit function with respect to prices in this case depends on the value of γ/ψ instead of just $1/\psi$. An increase in γ operates exactly like an equivalent reduction in the markup coefficient and vice versa. Hence, decreasing returns to scale makes a negative uncertainty-investment relationship more likely, whereas increasing returns offsets imperfect competition, bringing the uncertainty-investment relationship closer to the result of Hartman and of Abel.¹⁸

Overall, the results of this paper suggest that the relationship between changes in price uncertainty and capital investment under risk neutrality is not robust. Studying different adjustment-cost mechanisms is extremely important in determining the dynamics of investment and its business-cycle implications; however, it is very likely that it will be necessary to turn back to risk aver-

sion, incomplete markets, and lack of diversification to obtain a sturdier negative relationship between investment and uncertainty. Craine (1989) and Zeira (1989) have taken important steps along these lines.

APPENDIX

Consider the following discounted infinite-horizon version of the optimization problem presented in the paper for the perfect-competition case:

$$(A1) \quad V(K_{t-1}, Z_t) = \max_{I_t} \{ hZ_t^\eta K_t - I_t \\ - [I_t > 0] \gamma_1 I_t^\beta \\ - [I_t < 0] \gamma_2 |I_t|^\beta \\ + \delta E_t[V(K_t, Z_{t+1})] \}$$

subject to

$$K_t = \lambda K_{t-1} + I_t$$

$$\lim_{T \rightarrow \infty} \delta^T E_t[V(K_{T-1}, Z_T)] = 0$$

$$K_{t-1} \text{ given.}$$

The parameters δ and λ correspond to the discount factor and 1 minus the depreciation rate, respectively, both being less than 1. Also assume that $Z_t = Z_{t-1}W_t$, where W_t is any strictly positive independently and identically distributed random variable with mean 1 and log-standard deviation σ .

From the insights given by the two-periods problem, it seems reasonable to guess a value function of the form

$$(A2) \quad V(K_{t-1}, Z_t) = A(Z_t) + chZ_t^\eta K_{t-1}$$

where c is a constant and $A(\cdot)$ is a continuous function, both to be found.

After substituting (A1) into (A2) and obtaining the first-order conditions, it is possible to write investment as a function of the

¹⁸ It is also easy to show that if there are costs of waiting to invest, in the sense that there are some advantages (besides the traditional convex-adjustment-costs arguments) of planning and investing with time, the investment-uncertainty relationship may become positive even when adjustment costs are asymmetric, returns to scale are constant or decreasing, and competition is very imperfect.

unknown parameter c :

$$I_t = \begin{cases} \left[\frac{hZ_t^\eta(1 + c\lambda\delta L(\eta, \sigma)) - 1}{\gamma_1\beta} \right]^{1/(\beta-1)} & \text{for } I_t > 0 \\ - \left[\frac{1 - hZ_t^\eta(1 + c\lambda\delta L(\eta, \sigma))}{\gamma_2\beta} \right]^{1/(\beta-1)} & \text{for } I_t < 0 \end{cases}$$

where $L(\eta, \sigma) = E_t[W_{t+1}^\eta]$, an increasing function of σ (Jensen's inequality). Plugging this back into the Bellman equation makes it possible to find c :

$$c = \frac{\lambda}{1 - \lambda\delta L(\eta, \sigma)}.$$

This substitution also leads to a functional equation for $A(\cdot)$:

$$(A3) \quad A(Z_t) = \delta E_t[A(Z_{t+1})] + G(Z_t)$$

where

$$\begin{aligned} G(x) \equiv & - \left[x \geq \{h[1 + c\lambda L(\eta, \sigma)]\}^{-1/\eta} \right] \\ & \times \left[\frac{hx^\eta[1 + c\lambda\delta L(\eta, \sigma)] - 1}{\gamma_1\beta} \right]^{1/(\beta-1)} \\ & \times [1 - c\delta L(\eta, \sigma)hx^\eta] \\ & - \left[x \geq \{h[1 + c\lambda L(\eta, \sigma)]\}^{-1/\eta} \right] \\ & \times \gamma_1 \left[\frac{hx^\eta[1 + c\lambda\delta L(\eta, \sigma)] - 1}{\gamma_1\beta} \right]^{\beta/(\beta-1)} \\ & + \left[x < \{h[1 + c\lambda L(\eta, \sigma)]\}^{-1/\eta} \right] \\ & \times \left[\frac{1 - hx^\eta[1 + c\lambda\delta L(\eta, \sigma)]}{\gamma_2\beta} \right]^{1/(\beta-1)} \\ & \times [1 - c\delta L(\eta, \sigma)hx^\eta] \\ & - \left[x < \{h[1 + c\lambda L(\eta, \sigma)]\}^{-1/\eta} \right] \\ & \times \gamma_2 \left[\frac{1 - hx^\eta[1 + c\lambda\delta L(\eta, \sigma)]}{\gamma_2\beta} \right]^{\beta/(\beta-1)}. \end{aligned}$$

Making the simplifying assumption that W_t has bounded support makes the function $G(x)$ a continuous bounded function. This, together with the Markov structure of the transition and the fact that $\delta < 1$, determines that $A(Z_t)$ exists and is unique (David Blackwell, 1965).¹⁹

As long as $\lambda\delta L(\eta, \sigma) < 1$, the instantaneous reward function is concave in the control I_t ; therefore, the investment function is also unique. Furthermore,

$$\begin{aligned} \frac{\partial I_t}{\partial \sigma} &= \{\beta(\beta-1)([I > 0]\gamma_1 + [I < 0]\gamma_2) \\ &\quad \times (1 - \lambda\delta L(\eta, \sigma))^2\}^{-1} \\ &\quad \times |I_t|^{-1/\beta} hZ_t^\eta \delta \lambda^2 L_\sigma(\eta, 0) \\ &> 0 \end{aligned}$$

confirming the fact that the result of Hartman (1972) and Abel (1983, 1984, 1985) extends to the asymmetric-adjustment-cost case.

¹⁹Note that the function $A(\cdot)$ does not need to be unique to guarantee a unique investment function.

Savings and Wealth in Models with Altruistic Bequests

By WILLIAM LORD AND PETER RANGAZAS*

During recent years much attention has been given to the role of bequests in explaining various aspects of economic behavior. For example, authors have studied the impact of bequests on physical wealth accumulation (Laurence Kotlikoff and Lawrence Summers, 1981), the interest elasticity of savings (Owen Evans, 1983), tax reform (Laurence Seidman, 1984), and the distribution of wealth (Alan Blinder, 1976a).

More recently, economists have begun to distinguish between human and physical bequests (Gary Becker and Nigel Tómes, 1986). Acknowledging the presence of bequest in human form is important in analyzing each of the issues mentioned above. Outlays on children affect the shape of the family's labor supply and expenditure profiles, upon which the level of aggregate savings crucially depends. If these outlays are interest-sensitive substitutes for physical bequests, they will also influence the interest elasticity of savings. In the area of tax reform, the neutrality of the consumption tax depends on the ability of the government to identify human capital bequests from general consumption (Raymond Batina, 1987). If this is not possible, the "portfolio-choice" of investment in human versus physical capital may be distorted at the margin. Finally, the unequal transmission of wealth across generations may be explained by the lack of physical bequests and the inefficiently low levels of human bequests made by wealth-constrained households (Becker and Tómes, 1986). To distinguish clearly the behavior of constrained households from unconstrained households, who make sizeable physical be-

quests, both types of bequests must be recognized.¹

This paper introduces a model that makes explicit examination of these issues possible. It extends Lord's (1989) multiperiod model of life-cycle savings and adult human capital investment by adding altruistically motivated human and physical bequests.² The model is calibrated using microeconomic data on earnings, time and goods expenditures on children's human capital, and physical bequests. We then use the model to examine the contribution of bequests to wealth accumulation and the level of savings. This topic is the source of an important but yet unresolved debate between Franco Modigliani (1988) and Kotlikoff (1988). Kotlikoff maintains that U.S. wealth accumulation is primarily the consequence of bequests, as opposed to life-cycle savings for retirement. One type of evidence cited by Kotlikoff comes from simulation results demonstrating the failure of realistically calibrated life-cycle models to generate sufficiently high saving rates and wealth:income ratios (Alan Auerbach and Kotlikoff, 1987). We show, however, that if a pure life-cycle

¹In addition to these theoretical considerations, human bequests are worthy of study because they are likely to be much larger than financial bequests in the aggregate (Blinder, 1976b p. 90). We form estimates of the relative shares of wealth devoted to human and physical bequests in the Appendix.

²Evans (1983) and Seidman (1983, 1984) augment the standard life-cycle savings model with physical, but not human, bequests. Evans briefly considers a simple dynastic model of altruistic bequests but concentrates primarily on ad hoc bequest formulations which are not derived from utility maximization. Seidman uses the "taste-for-bequest" model, in which the source of satisfaction is the level of bequest per se. This formulation immediately encounters difficulties when both human and physical bequests are included. Unless the price of the inputs in human capital formation equals the price of physical bequests, the household will be at a corner, leaving all physical or all human bequests, depending on which is cheaper.

model generates low aggregate savings rates, then augmenting the model with altruistic bequests that mimic available microdata will not necessarily cause the savings rate to rise significantly.

I. The Model

The general altruistic approach to bequests has been developed most recently by Becker (1981) and Becker and Tomes (1986).³ It presents a natural and parsimonious theory of the case in which both human and physical bequests are made. Our model is a special case of this paradigm designed to facilitate comparisons to the standard life-cycle simulation model found in the literature (Summers, 1981; Evans, 1983; Auerbach and Kotlikoff, 1987).

We begin by describing the age structure, wealth constraint, and production technologies of the model. Individuals are economically dependent on their parents through age 20. At age 21, they begin their independent economic lives. At age 26, the unisex individual "produces" 1.3 children, which corresponds to a population growth rate of 1 percent. Retirement occurs at age 63, and individuals die after 78 years of life. At this time, physical bequests are left to the next generation. Inheritance is, therefore, received at age 53.

Each individual begins his economic life with an initial quantity of nondepreciating human capital,⁴ based on his parent's investment, which augments his adult human capital stock in an additive fashion. Throughout economic life, individuals choose levels of family consumption, goods and human inputs for their children's development, and the level of a physical bequest inclusive of interest received and taxes paid, as well as time and goods inputs for their own adult human capital development.

The modeling of adult human capital decisions is based on Yoram Ben-Porath (1967). During adult years, the production function for gross additions to the stock of human capital follows a Cobb-Douglas specification with decreasing returns to scale and constant output elasticities. Human capital produced during adulthood is assumed to depreciate at a constant rate, d . The technology constraining a child's human capital production is distinct from that of adults, although of the same basic Cobb-Douglas form. The human capital production function for children is

$$(1a) \quad Q_t = \nu (s_t H_t)^{\gamma_t} (D_t)^{\lambda_t}$$

$$(1b) \quad \gamma_t = \frac{\gamma_0}{(1 + \alpha)^{t - t_0}}$$

$$(1c) \quad \lambda_t = \frac{\lambda_0}{(1 + \beta)^{t - t_0}}$$

where, ν , γ_0 , λ_0 , α , and β are constants and where $t_0 = 26$, the first year of investment in children. Equation (1) allows the output elasticities of parental time and goods inputs to vary with the age of the child. This is necessary to capture certain stylized facts which are discussed in the Appendix.

For comparative purposes, we employ the familiar constant-elasticity-of-substitution utility function (Summers, 1981; Evans, 1983; Auerbach and Kotlikoff, 1987) augmented with altruistic preferences toward the next generation;

$$(2) \quad U = \frac{1}{1 - 1/\sigma}$$

$$\times \left[\sum_{t=1}^{58} C_{20+t}^{1-1/\sigma} (1 + \delta)^{-(t-1)} + m(1.01)^{26} U_* (1 + \delta)^{-57} \right]$$

where σ is the intertemporal elasticity of substitution in consumption, δ is the pure

³Paul Menchik and Martin David (1983) also discuss this model and trace its origin to Alfred Marshall.

⁴For the typical household, basic reading, writing, and arithmetic skills, as well as health habits, are likely to be maintained by the daily experiences of production and consumption. For this reason, the initial stock of human capital is not subject to depreciation.

rate of time preference, U_* is the utility of a member of the next generation, and m is the relative preference for U_* versus own lifetime consumption. The microeconomic solutions are obtained in the manner of Batina (1987). In the steady state, where $U = U_*$, the first-order conditions of this otherwise complex problem collapse to a rather simple form, including

$$(3) \quad m(1 + \delta)^{-57} = (1 + r)^{-26}.$$

A special case of this model takes $m = 1$ and assumes nonoverlapping generations, which reduces (3) to the familiar condition, $r = \delta$.

Equation (3) indicates that the net interest rate is completely determined by taste and demographic parameters, implying an infinitely elastic partial-equilibrium supply of capital. As a result, bequests, and thus savings, are indeterminate at the micro-level. To obtain a solution, values for all parameters, as well as initial values for r and bequest, are assumed. First, the efficient human capital decisions are computed. Next, the consumption choices are solved for in terms of the bequest. Consumption is then aggregated across cohorts using single-period resource constraints, to obtain an expression for the aggregate stock of assets. This, along with the aggregate effective labor supply, determines the capital:labor ratio. Substituting the capital:labor ratio into the profit-maximizing condition generates a gross interest rate. Bequests are adjusted until the interest rate generated is in agreement with the initially specified r . Successive trials lead to a choice of r best satisfying the stylized facts (see Appendix).

II. Initial Baselines and Savings Rates

Setting the parameter values of a simulation model is a critical step in the modeling process. The exact approach taken depends on the availability of empirical information and the purpose of the study. We use three different methods of setting the parameter values of our model. First, empirical estimates of the parameters are used, when

they are available and precise. The empirical literature typically produces a range of estimates for a parameter. Rather than utilize the full range, we choose to focus on the upper and lower bounds. We collect the upper-bound estimates into what is called the "high-response" (H) case, since these estimates suggest relatively large behavioral responses and high interest elasticities. The lower-bound estimates are collected in the "low-response" (L) case to reflect the other extreme.

Second, other parameters are set in order to produce stylized facts regarding descriptive aspects of household behavior, for example, the expenditure shares on various goods. Finally, to facilitate comparisons to existing models, any remaining free parameters are to be set equal to values chosen by previous authors.⁵ A detailed account of this procedure is presented in the Appendix.

We consider six baselines in total, with a high (H) and low (L) response case for each of three assumptions made about the share of lifetime wealth devoted to bequests. Our review of the available evidence yields three different estimates of the bequest share: 1, 2.5, and 4 percent (see Appendix). Table 1 presents the simulations for a number of variables under each case.

The range of the Modigliani wealth share (row 5), aggregate inheritance divided by aggregate wealth, includes the estimates obtained by Modigliani and by Kotlikoff and Summers (see Modigliani, 1988 p. 28). Using methods entirely independent from ours, Modigliani produces an estimate of 17 percent, compared to Kotlikoff and Summers's estimate of 46 percent. Thus, their estimates are consistent with the micro-bequest

⁵Since the purpose of our paper is to provide a counterexample to commonly held beliefs about the role of bequests in aggregate savings, this procedure is appropriate. This is not to say that we conduct no sensitivity analysis. Recall that we provide high- and low-response cases and, in addition, experiment with functional forms and unknown parameters as mentioned in the Appendix. However, if the study were designed to test alternative theories or to provide recommendations, a more thorough sensitivity analysis of the free parameters should be conducted.

TABLE 1—STEADY-STATE BASELINES

Case variable	Bequest share					
	1%		2.5%		4%	
	H	L	H	L	H	L
Savings rate ^a	4.0	3.5	4.2	3.8	4.3	4.0
Interest rate ^b	5.0	5.7	4.8	5.3	4.6	4.9
Marginal propensity to bequeath ^c	0.27	0.25	0.29	0.27	0.30	0.28
Expenditure share ^d	5.2	3.9	5.4	4.3	5.6	4.6
Modigliani wealth share ^e	0.14	0.27	0.32	0.49	0.47	0.62
Wealth share including interest ^f	0.26	0.54	0.59	0.96	0.83	1.15
Flow share ^g	0.01	0.01	0.01	0.02	0.02	0.03
Savings rate ^h (no human bequest)	4.2	3.6	4.3	3.9	4.5	4.2
Savings rate ⁱ (no bequests)	4.0	3.3	4.0	3.2	3.9	3.1

Note: H and L are the high- and low-response cases.

^aAggregate savings divided by aggregate output.

^bThe net of tax interest rate, with a tax rate of 20 percent.

^cIncrease in the present value of financial bequests following a one-unit increase in parents' wealth.

^dThe present value cost of time and goods inputs allocated to children's human capital divided by human wealth.

^eTotal inheritance wealth divided by total wealth.

^fAdds interest income from inheritance to Modigliani wealth share.

^gThe flow of bequests divided by total wealth.

^hAggregate savings divided by aggregate output when the efficient level of young human capital is costlessly provided.

ⁱAggregate savings divided by aggregate output when there are no human or financial bequests.

share estimates we constructed from previous cross-sectional empirical studies and simulation models. The next row (row 6) includes the potential interest income earned on inheritances in the numerator and again produces numbers comparable to the Modigliani and Kotlikoff and Summers range of estimates (see Modigliani, 1988 p. 28).

A most surprising feature of our baselines is that the aggregate savings rates (row 1) show little variation across bequest-share assumptions. The upper-bound bequest-share case, despite producing Modigliani wealth-share estimates slightly above those obtained by Kotlikoff and Summers, continues to produce a savings rate in the neighborhood of 4 percent. Furthermore, this is only marginally higher than the savings rate obtained with the bequest motive removed and all other assumptions maintained (last row). This finding contradicts the commonly held belief that life-cycle models augmented with a bequest motive would produce sig-

nificantly higher savings rates. For example, based on his work with Auerbach, Kotlikoff points out that realistically calibrated life-cycle simulation models have difficulty generating realistic savings rates, especially when the consumption of children is included (Kotlikoff, 1988 p. 48; Auerbach and Kotlikoff, 1987 pp. 64, 168). In the version of their model which excludes children, Auerbach and Kotlikoff report a savings rate of 3.7 percent, a value within the range of our no-bequests steady-state figures (last row of Table 1), where we assume that the previously endogenous level of young human capital is costlessly provided and there is no bequest motive. This rate of savings is substantially below either private or national savings of the postwar period, with the exception of the national rate in the last ten years.⁶ When they add the consumption

⁶See Michael Boskin (1988 table 3).

of children, they are also forced to add a positive government capital stock to maintain reasonable levels of aggregate wealth. They claim that this "...provides further evidence of the inadequacy of the pure life-cycle model without bequests to explain observed rates of capital accumulation" (p. 168).

Our full-model savings rates (first row), suggest that the bequest motive does offset the reduction in savings resulting from expenditures on children, without the need of government savings. However, this is misleading. As mentioned in the Appendix, we deliberately underestimate expenditures on children in order to reflect something closer to pure investment expenditures. More importantly, the model with financial bequests but no human capital expenditures on children (second to last row of Table 1), again yields only marginally higher rates of savings than the full model. Thus, in our model, the impact of financial and human bequests has very little effect on physical capital accumulation. There appears to be a substitution between the different types of savings and the different types of expenditures, so as to leave total savings rates essentially unchanged.

This can best be explained by starting with the full model and then carrying out the Kotlikoff and Summers (1981) thought experiment of eliminating the bequest motive. First, consider the elimination of human bequests, while adjusting the altruism parameter to keep the physical inheritance share constant. This has a positive wealth effect upon parents, through reduced expenditures. Consequently, increased consumption significantly dampens any increase in life-cycle savings. For the most part, consumption, (and not life-cycle savings) is substituted for human capital expenditures on children.

Second, suppose financial bequests are also removed. Again, savings rates fall only slightly. This is due to the wealth effects associated with the elimination of financial bequests. As is well known, so long as the interest rate r exceeds the (effective) population growth rate g , bequests generate positive net-of-bequest inheritance wealth. In the present case, r exceeds g by almost 4

percent, on average. Consequently, a large part of the inheritance is used to finance life-cycle consumption. As a result, eliminating financial bequests causes an increase in life-cycle savings to preserve retirement consumption, leaving savings rates virtually unchanged.

The savings rates do fall by relatively greater amounts in the low-response case. In this case, as bequests are removed and interest rates rise, the decrease in human capital expenditures and consumption is smaller than in the high-response case. As a result, the offsetting increase in life-cycle savings is smaller. Thus, substitution effects (and not wealth effects alone), play a role in the results. However, even when assuming lower-bound responses, bequests make a small contribution to aggregate savings.

III. Conclusion

It has been argued in the literature that incorporating bequests into life-cycle simulation models may raise savings rates to more reasonable levels. We have shown, for the initial levels of savings generated by realistically calibrated life-cycle models, that adding bequests will not significantly alter savings rates. Adding or subtracting human and financial bequests in a life-cycle model causes indirect wealth effects on lifetime consumption, which serve to offset the direct impact on savings. The offsetting wealth effect is relatively large when the difference between the steady-state interest rate and the effective population growth rate is relatively large. For a given population growth rate, the size of this gap is driven by the underlying level of life-cycle savings. The lower the level of life-cycle savings, the larger is the gap and the smaller is the effect on savings from altering the level of bequests.

APPENDIX

As in Lord (1989) and Auerbach et al. (1988), adult human capital production parameters are chosen to approximate an age-wage profile reported by Finis Welch (1979) and to reflect estimates of the returns to scale (James Heckman, 1976), of

human capital decay (Heckman, 1976; B. F. Kiker and Blaine Roberts, 1984), and of the time and goods input shares (Boskin, 1975). These considerations suggest two adult human capital parameter-value combinations, one with high returns and low decay (0.75 and 0.08) used in the H case and another with low returns and high decay (0.45 and 0.12) used in the L case. Both combinations have a time input share of 0.67.

A survey of the empirical literature studying family expenditures on children reveals five general stylized facts. These deal with the total lifetime budget shares to human and physical bequests, the portion of total human capital investments made in the form of goods versus time, and the profiles of the parents' time and goods inputs during the child's period of dependence.

Boone Turchi (1975) estimated the present value of parental outlays on children through the college years to be approximately 6.5 percent of human wealth. Thomas Espenshade (1984) expanded the expenditure categories used by Turchi to include approximately 50 percent more before-college goods inputs. Accounting for the expanded expenditure categories increases the total estimate to 7.6 percent of human wealth. The latter estimate also makes the shares of time and goods inputs roughly equal. Without a doubt, many of these expenditures are for consumption rather than investment purposes. Consequently, when calibrating the model, we kept the total expenditure share out of human wealth between 3 and 6 percent.

The expenditure share (in present value) of human wealth devoted to bequests can be expressed as $[(1+g)/(1+r)]^N [\pi/(1-\pi)]$, where π is the present value of inheritance as a fraction of total wealth. Let $N = T_y + 1 + n$, with T_y being the age in the last year of economic dependence and n being the number of years waited, after economic independence, before having children. Thus, N is the age gap between generations. The Survey Research Center's 1960 "Income and Welfare" survey of inheritances yields an average π , for the population, of 2.5 percent (see James Davies, 1982 pp. 473-4). Independently, Blinder (1973) and Davies

(1982), using empirically grounded micro-simulations, generate an average π of 5 or 6 percent. With g set equal to 1 percent, the after-tax interest rate set equal to 3 percent, and a value of N equal to 26 years ($T_y = 20$ and $n = 5$), these inheritance figures give a range of estimates for the bequest share between 1.5 and 3.2 percent.

Menchik and David (1983) find a bequest share of 10 percent for the top quintile in their sample. Lower quintiles in their sample also exhibit positive shares, but they are unstable in value across age cohorts and are unresponsive to changes in wealth, unlike the shares in the upper quintile. It seems likely that the majority of bequests left by the lower quintiles were accidental rather than altruistically planned. Setting the bequest shares of the lower four quintiles to zero and assuming that 40 percent of human wealth is owned by the top quintile gives an average bequest share for the population around 4 percent. In our simulations, we chose to reflect the range of available evidence by producing aggregate savings rates under three different shares: 1, 2.5, and 4 percent.

Finally, a recent study by Joseph Hotz and Robert Miller (1988) presents some information on the time profile of parents' time and goods inputs. They estimate that parents devote about 660 hours to child care in the initial year of dependency. With 16 hours of discretionary time per day, this translates to approximately 5 percent of the yearly time endowment. After the first year, they estimate the time input to decline geometrically at a rate of 12 percent. They also could not reject the hypothesis that goods inputs had a constant profile. This seems to be roughly consistent with the slightly humpbacked expenditure profile we computed from estimates in Espenshade (1984).

These facts regarding expenditures on children can be mimicked by appropriately setting the parameters of the children's human capital production function. The values for α and β [see equations (1b) and (1c)] were chosen to approximate the time and goods input profiles and relative expenditure shares. The efficiency scalars in adult and young human capital production and

the returns to scale in the children's production function were then set to generate the values of total expenditures relative to human wealth and the magnitude of adult production relative to the bequeathed stock.

The three taste parameters are the rate of time preference δ , the intertemporal substitution elasticity σ , and the taste for bequest parameter m . Recent estimates by Robert Hall (1988), using aggregate data, suggest that σ is not likely to be much above 0.10. The most recent estimates using micro-data are those obtained by Thomas MaCurdy (1981). They place an upper bound of σ at 0.45. We construct baselines, with $\sigma = 0.15$ (L case) and $\sigma = 0.4$ (H case). In our reported results, δ is set at 0.01 in all cases, a value intermediate to those assumed by Summers (1981), Evans (1983), and Auerbach and Kotlikoff (1987). We also conducted the experiments with $\delta = 0.03$, the highest value found in the literature, and none of the qualitative conclusions were altered. Evans is the only researcher to set δ below 0.01. Since most economists regard δ to be positive, we did not consider negative values. As mentioned, bequest parameters are set to produce bequests of 1, 2.5, and 4 percent of human wealth.

In addition to the altruistic model reported in the text, we considered the case in which the next generation's wealth, as opposed to utility, entered the current generation's utility function. We looked at this model with both homothetic and nonhomothetic utility functions. For the parameter settings just described, these models produced very similar results and are apparently close substitutes to the formulation used in the text for the issues at hand. In future work, we plan a more thorough examination of different altruistic specifications.

A New Estimate of the Welfare Loss of Excess Health Insurance

By ROGER FELDMAN AND BRYAN DOWD*

In a classic article, Martin S. Feldstein (1973) argued that American families are in general overinsured against medical care expenses. If insurance were reduced, the utility loss from increased risk would be more than outweighed by the gain from lower prices and reduced purchase of excess medical care. Raising the average coinsurance rate from 0.33 to 0.67 would produce a net gain of \$27.8 billion (in 1984 prices) in the private hospital sector, according to Feldstein's "most likely" parameter values.

To make his estimate, Feldstein assumed values for the following parameters: the price elasticity of demand, consumer risk-aversion, the gross price change resulting from lower insurance coverage, and the decrease in health-care quality induced by lower insurance coverage. While the actual values of the last two parameters are still somewhat problematic, more recent and much-improved estimates of the price elasticity of health-care demand and risk-aversion are now available. The Rand Health Insurance Experiment has shown that consumers randomly assigned to a free health-care plan spent 46 percent more than those in a plan with 95 percent coinsurance (Willard G. Manning et al., 1987). The price elasticity of demand for a constant coinsurance policy is in the -0.1 to -0.2 range, values that are at the lower end of those in the nonexperimental literature, and less elastic than the -0.4 to -0.8 range used by Feldstein.

Improved estimates of the degree of consumer risk-aversion were also produced

by the Health Insurance Experiment (M. Susan Marquis and Martin R. Holmer, 1986). Families in all plans (except the free-care plan) faced a maximum limit on out-of-pocket expenditures in any year. At the end of its participation in the experiment, each family was asked if it would be willing to pay a predetermined premium to reduce this limit. From the resulting offers, one can calculate the Pratt-Arrow absolute risk-aversion parameter (John W. Pratt, 1964; Kenneth J. Arrow, 1974). Similar estimates are available from Bernard Friedman's (1974) study of health-plan choice by Federal employees. These data suggest that consumers are considerably more risk-averse than Feldstein assumed.

The purpose of this paper is to calculate new estimates of the welfare loss of excess health insurance, using the Rand data on price elasticity and consumer risk-aversion. Manning et al. (1987) reported the dead-weight loss from insurance in a recent issue of this journal. According to Manning et al. (1987), individuals in the free-care plan spent \$344 more, on average, than those in the 95-percent coinsurance plan. The welfare gain per person from reducing insurance coverage was calculated at approximately $\$344(1 - 0.31/2) = \291 (in 1984 prices), where 0.31 is the average coinsurance rate.¹

These calculations assume that gross medical-care prices are constant. This assumption affects not only Manning et al.'s (1987) estimate of the welfare loss of excess health insurance, but also their explanation

*University of Minnesota, School of Public Health, Division of Health Services Research and Policy, 420 Delaware Street SE, Box 729, Minneapolis, MN 55455. Feldman is also in the Department of Economics, University of Minnesota. The authors acknowledge helpful comments from Will Manning.

¹Because the maximum limit on out-of-pocket expenses in the 95-percent plan was capped at \$1,000, these individuals faced an average coinsurance rate of 0.31. An upper bound on the welfare-loss calculation comes from assuming that they valued the last dollar of medical-care spending at 31 cents.

of the relationship between increased health insurance and health-care expenditures over the period from 1950 to 1980. It is unlikely that gross price would remain constant if health insurance coverage were altered on a national scale. Feldstein (1971, 1973) suggests that gross price would fall if coverage were reduced, although the exact size of the price decrease is uncertain.

Further, a change in health insurance might induce changes in product quality. In Feldstein's model, the hospital changes quality by changing the input mix. Manning et al. (1987) cite a different effect of insurance: its stimulus on technological change. However, the extent to which insurance induces changes in input mix and technology is not clear, nor is the effect of these changes on consumer demand. Consequently, we simulate several changes in gross medical-care prices in our analysis, including the baseline case of constant prices.

Finally, in concentrating on the dead-weight loss from moral hazard, Manning et al. (1987) did not consider the benefits of insurance, namely, the reduction in financial risk. While not taking issue with Manning et al.'s (1987) basic conclusions—that health insurance encourages excess consumption, but that health insurance cannot account for much of the increase in total health care spending at constant prices—we suggest that the welfare-loss calculation can be refined to include gross price and risk-bearing effects.

The exact welfare-loss calculation depends explicitly on the utility function and the statistical distributions of expenditures for outpatient visits, hospital admissions, and length of stay. The calculation can be much simplified by using Pratt's (1964) derivation of the cost of risk-bearing. Assuming only that the utility function is separable and that third (and higher) moments of the distribution of expenditures can be ignored, we can easily derive the relevant expression needed to calculate welfare loss. An estimate of the error from ignoring higher moments is presented in the Appendix.

Let the utility function be separable in nonmedical-care consumption and medical

care. Denote these two parts of the utility function as W and V , respectively. We want to find the *pure risk premium*, π , such that expected utility with health insurance is equal to expected utility without insurance:

$$\begin{aligned} (1) \quad & E[V(X - \pi - (1 - c)E(PM) \\ & - cPM) + W(M)] \\ & = E[V(X - pm) + W(m)] \end{aligned}$$

where X = fixed level of income; c = coinsurance rate, M = quantity of medical care consumed with insurance, m = quantity of medical care consumed without insurance, P = gross price of medical care with insurance, and p = gross price without insurance. Both sides of equation (1) involve expected values, since M and m are random variables. By definition, out-of-pocket spending for medical care is cPM with insurance and pm without insurance.

The Rand Health Insurance Experiment showed that M exceeds m because of moral hazard. Feldstein's hypothesis is that P is higher than p because of the induced price increase resulting from insurance. Finally, we assume that the insurance premium is actuarially fair: that is, premium equals $(1 - c)E(PM)$.

Taking Taylor series expansions of equation (1) (see the Appendix), we can solve for π :

$$\begin{aligned} (2) \quad \pi = & [E(pm) - E(PM)] \\ & + \frac{[E(W(M)) - E(W(m))]}{V'} \\ & + \frac{R\sigma^2}{2}. \end{aligned}$$

The first two terms on the right-hand side in equation (2), enclosed by brackets, represent the welfare loss due to higher spending on medical care with insurance. The next two terms in brackets represent the value of increased medical care to consumers. This value can be approximated by a consumer surplus triangle, assuming that the demand

curve for medical care is linear. To calculate these terms, we relied on estimates from Manning et al. (1988) of total family spending (out-of-pocket payments and insurance payments) for medical, dental, and mental health care.² In 1967 dollars, families in the free-care plan spent \$943 on average, while those in the 95-percent coinsurance plan spent \$606 on these services.

The last term is the value of risk-avoidance provided by insurance. This term is positive, and it increases as the variance of out-of-pocket spending increases or as consumers become more risk-averse. R is the Pratt-Arrow absolute risk-aversion parameter, defined as $R = -V''/V'$. Values of R can be obtained from Marquis and Holmer (1986), who found that consumers would pay up to \$634 to avoid a bet with equally probable outcomes of \$0 and -\$1,000 in 1982 dollars (i.e., an expected value of -\$500). Thus the "pure risk premium" for this bet was \$134. Changing the odds of the \$1,000 loss to 0.9 resulted in a pure risk premium of \$38 (although the expected loss is larger, the pure risk premium is lower because the loss is almost a "sure thing" at 0.9 odds). These were illustrative cases for families characterized as "healthy" and "sick," respectively. The information contained in these bets can be utilized to solve for values of R between 0.0028 and 0.0036.³

²See Manning et al. (1988 table B.6) for family spending data in nominal dollars. We converted these data to real (1967) dollars using information supplied by Will Manning that the ratio of nominal to real total spending in the 95-percent coinsurance plan was approximately 2.0.

³Values for the absolute risk-aversion parameter can be obtained by solving $\pi = R\sigma^2/2$ for the given values of $\pi = 134$ with $\sigma^2 = 250,000$ and $\pi = 38$ with $\sigma^2 = 90,000$. These are the pure risk premiums and variances of the bets offered by Marquis and Holmer (1986). The solutions are $R = 0.0011$ or $R = 0.00084$. Since Marquis and Holmer's bets were offered in 1982 dollars, R is also expressed in 1982 dollars. R values must be converted to real (1967) dollars by multiplying them by the ratio of 1982 medical care CPI (consumer price index) to 1967 medical care CPI. The medical care CPI stood at 92.5 in 1982 and 28.2 in 1967 (*Economic Report of the President*, 1989 table B-59). Thus, R values were adjusted to obtain, for example, $0.0011(92.5/28.2) = 0.0036$. Friedman (1974) estimated

Friedman (1974) estimates that $R = 0.00265$ or 0.0028.

The variance used in equation (2) should be adjusted by characteristics of families enrolled in the 95-percent coinsurance plan.⁴ Instead, the only information available to us was the total variance of out-of-pocket spending in the 95-percent coinsurance plan. This variance, which was \$25,828 in 1967 dollars, is an upper bound on the adjusted variance. However, as Joseph Newhouse (1982) and Newhouse et al. (1989) have shown, the maximum explainable variance in medical expenditures is only about 15-20 percent of total variance. Assuming that the maximum explainable percentage of variance in out-of-pocket expenditures is also 15-20 percent, the error from using our upper-bound estimate is small.

Table 1 presents the results of our calculation, expressed as the welfare loss from increasing coverage from 95-percent coinsurance to free care. Following Manning et al. (1987), we assumed that families value the last dollar of medical care spending at either 31 cents or 95 cents. To illustrate our calculations, use the first assumption and suppose that insurance causes the gross price of medical care to rise by 20 percent. Then the welfare loss per family, before considering risk-bearing, is $(943 - 606)(1 - 0.31/2) + (943)(0.2) = \474 in 1967 dollars. This estimate is converted to 1984 dollars by using the medical-care price index: $(474)(106.8/28.2) = \$1,795$.⁵ Estimates for each family were multiplied by the total number of U.S. households in 1984 headed

that R was 0.0025 or 0.00265 in 1968 dollars. These estimates were also converted to 1967 dollars. We used the value of R obtained from Marquis and Holmer's first bet in our calculations, but we also used Friedman's estimate to test the sensitivity of the calculations.

⁴The relevant variance is of family expenses, not individual expenses. To the extent that individual expenses are less than perfectly correlated, the family acts as its own risk pool, reducing the variance in medical expenses.

⁵The medical-care price index was 28.2 in 1967 and 106.8 in 1984 (*Economic Report of the President*, 1989 table B-59). The ratio of 106.8/28.2 was used to update gains and losses from insurance to 1984 dollars.

TABLE 1—THE WELFARE LOSS OF EXCESS HEALTH INSURANCE (BILLION 1984 \$)

Gross price change	Value of marginal dollar of medical spending	
	31 Cents	95 Cents
No change	61.0	33.4
10-percent increase	85.0	57.4
20-percent increase	109.3	81.7

Note: Table 1 assumes that the risk-aversion parameter is 0.0036 and that the variance of out-of-pocket spending under the 95-percent coinsurance plan is \$25,828.

by a householder under age 65: $(\$1,795)(67,506,000) = \121.2 billion.⁶

The gain from risk-bearing is $(0.0036) \times (25,828)/2 = \46.49 per family in 1967 dollars. This can be converted to \$176 per family in 1984, or \$11.9 billion for all U.S. households headed by persons under age 65. While not inconsequential, this gain is not large enough to outweigh the loss due to excess consumption of medical care. Utilizing other values for the risk-aversion parameter would proportionately change this estimate. For example, if the risk-aversion parameter were 0.0028, as implied by Friedman's study or Marquis and Holmer's lower estimate, the gain from risk-bearing would be \$137 per family in 1984.

Table 1 shows that the net welfare loss from excess health insurance is always positive. Utilizing the example discussed above, the net loss is $\$121.2 - \$11.9 = \$109.3$ billion. This is the maximum loss, which occurs if insurance induces a large increase in gross price and consumers place low marginal value on medical spending. Under assumptions of constant prices and high marginal valuation, welfare loss would fall to \$33.4 billion.

The calculations presented in Table 1 are sensitive to the assumed increase in gross price induced by insurance. Since it is prob-

lematic how much (if any) additional product quality is reflected by these price increases, the estimates should be regarded as largely illustrative. This feature of the calculations deserves further study.

In conclusion, we have provided a new estimate of the welfare loss of excess health insurance. We used the Rand Health Insurance Experiment results regarding demand effects and risk-aversion. In addition, insurance was hypothesized to affect the gross price of medical care. Accounting for these factors, we suggest that the range of welfare loss is from 33.4 to 109.3 billion dollars in 1984. While agreeing with Manning et al.'s (1987) basic conclusion, we believe that our approach refines their estimate by including the gains from risk-bearing.

Finally, the calculations presented here compare an insurance policy with a \$1,000 cap on out-of-pocket expenditure with a free-care policy. The free-care policy is found to be inferior from a welfare point of view. Since the Health Insurance Experiment did not observe families with *no* health insurance, the welfare gains or losses from a policy with a \$1,000 spending cap cannot be compared to the total absence of health insurance.

APPENDIX

Expand the left side of equation (1) by a first-order Taylor series at $X - \pi - (1 - c)E(PM) - cPM$ near $X - E(pm)$ to obtain

$$(A1a) \quad V + V'[-\pi - E(PM) + E(pm)] \\ + E[W(M)]$$

where V and all derivatives are evaluated at $X - E(pm)$. Take a second-order expansion of the right side of (1) at $X - pm$ near $X - E(pm)$:

$$(A1b) \quad V + \frac{V''\sigma^2}{2} + E[W(m)].$$

Equate (A1a) and (A1b) and solve for π . The solution is equation (2).

By using only a second-order expansion, equation (2) ignores third and higher mo-

⁶Families were excluded from the Health Insurance Experiment if the family head was eligible for Medicare at the beginning of the study or would become so by virtue of age before the end of the study. In 1984, there were 67,506,000 households headed by persons under age 65 (Bureau of the Census, 1985 table C).

ments of the distribution of out-of-pocket expenditures. We illustrate the error involved in this approximation by taking a fourth-order expansion, which yields equation (2) plus two additional terms:

$$-\frac{V^{[3]}\mu_3}{6V'} - \frac{V^{[4]}\mu_4}{24V'}$$

$V^{[n]}$ stands for the n th derivative of the utility function; μ_3 is the third moment, and μ_4 is the fourth moment of the distribution of risk. To evaluate these terms, we assume a constant absolute risk-aversion (CAR) utility function of the form

$$(A2) \quad V = -\frac{e^{-RX}}{R}$$

Take derivatives of this function:

$$V^{[3]} = R^2 e^{-RX} \quad \text{and} \quad V^{[4]} = -R^3 e^{-RX}$$

Substitute these above to get

$$-\frac{R^2\mu_3}{6} + \frac{R^3\mu_4}{24}$$

Estimates from the Rand Health Insurance experiment are $\mu_3 = \$3,420,235$ and $\mu_4 = \$1,596,966,296$ (in 1967 dollars). Using these estimates and Marquis and Holmer's (1986) value of $R = 0.0036$, we find that correcting for the third and fourth moments decreases the estimated gain from risk-bearing by \$4.29 per family in 1967 dollars, or \$16.25 in 1984 dollars. This correction is of a small order of magnitude, compared to the gain from risk-bearing of \$176 per family calculated from equation (2).

Estimates of the cost of risk-bearing that rely on the third and fourth moments of the distribution of risk are sensitive to outlier cases. Since this correction is neither large nor robust, we dropped it from equation (2).

Reconciling Recent Estimates of the Marginal Welfare Cost of Taxation

By DON FULLERTON*

Much of welfare economics has been plagued by differences in the concepts used to measure changes in consumer welfare. One example of this problem is presented in striking clarity by three recent papers in *The American Economic Review* that calculate "marginal excess burden" for U.S. labor taxes. This note shows that almost all of the differences in results can be traced to differences in the definition of "marginal excess burden."

Each of the three papers includes several special cases, but for comparability, I concentrate on their calculations in which the uncompensated labor-supply elasticity is zero and the marginal dollar is spent on a public good that is separable in utility. Their results are summarized in Table 1. Charles Stuart (1984) builds a simple two-sector general-equilibrium model and finds in this case that "marginal excess burden" (MEB) is 7 cents. Charles Ballard, John Shoven, and John Whalley (henceforth, BSW) (1985) use a more complicated general-equilibrium model in which their "MEB" is 12 cents. Edgar Browning (1987) employs a simple partial-equilibrium model and obtains a corresponding figure of 21 cents. He concludes that "almost all of the differences in results can be traced to different assumptions about key parameter values" (p. 11).

The next row of Table 1 shows that the substitution of Stuart's parameters into Browning's formula (given in a footnote to the table) only changes Browning's measure from 21 cents to 24 cents. Thus, the large difference in published results (21 vs. 7 cents) is not due to parameters.

Since important differences in the definitions were not explained in the three papers, I state the three definitions explicitly and illustrate them diagrammatically. Rather than present new analytical results,¹ I return to the exact model of Stuart (1984), replicate his calculation, and add the other two "MEB" measures. When Stuart's "MEB" is 7 cents, Table 1 shows that the BSW measure is also 7 cents. With the same equilibrium outcome, Browning's measure is 25 cents. Thus, the results differ because the definitions differ.²

I. Three Definitions of "Marginal Excess Burden"

Stuart (1984) uses the compensating surplus (CS) of John Hicks (1943, 1954), and he subtracts the actual change in revenue (dR) to get the change in excess burden. He then divides by the actual change in revenue to get the change in excess burden per dol-

*Department of Economics, University of Virginia, Charlottesville, VA 22901. This note is a revised portion of my 1989 working paper, "If Labor is Inelastic, Are Taxes Still Distorting?" written on a grant from the Olin Foundation to the National Bureau of Economic Research. I am grateful for computer programs and substantial help from Charles Stuart, for research assistance from Joon-Kyu Park, and for helpful suggestions from Charles Ballard, George Borjas, Anne Case, Lawrence Goulder, Yolanda Henderson, James Hines, Andrew Lyon, Joram Mayshar, Hilary Sigman, Jonathan Skinner, and referees.

¹Relevant analytical results appear in Anthony Atkinson and Nicholas Stern (1974), David Wildasin (1979, 1984), Stuart (1982), Robert Triest (1988), Steven Slutsky (undated), and Joram Mayshar (1988a, b). The three *American Economic Review* papers are specifically discussed in Ballard (1987), Ingemar Hansson and Stuart (1988), Triest (1988), Shaghil Ahmed and Dean Croushore (1988), and Mayshar (1988a).

²Similar definitional differences carry over to the literature on the "marginal efficiency cost of redistribution" and may explain much of the remaining difference between results of Ballard (1988) and Browning and William Johnson (1984).

TABLE 1—DIFFERENT MEASURES OF "MARGINAL EXCESS BURDEN" FOR U.S. LABOR TAXES

Source	$(CS - dR)/dR$ (Stuart)	$(EV - dR)/dR$ (BSW)	$(EV - dR^*)/dR$ (Browning)
From the literature ^a			
Stuart (1984)	0.07	—	—
Ballard, Shoven, and Whalley (1985)	—	0.12	—
Browning (1987)	—	—	0.21
Using Browning's (1987) model ^b with Stuart's (1984) parameters	—	—	0.24
Using Stuart's (1984) model ^c			
Other measures calculated	0.07	0.07	0.25
Labor unchanged with variable wage	0.00	0.00	0.20
Labor unchanged with fixed wage	0.00	0.00	0.24

Notes: CS = compensating surplus; EV = equivalent variation; dR = change in actual revenue using average tax rates; dR^* = change in revenue along curve compensated to new utility, using marginal rates.

^aEstimates from the literature all employ a zero uncompensated-labor-supply elasticity, where additional revenue is spent on government consumption, but they differ on other assumptions.

^bBrowning (1987) calculates the area between a fixed gross wage rate and an approximately linear compensated labor supply curve and shows that

$$\frac{EV - dR^*}{dR} = \left(\frac{m + 0.5}{1 - m} \right) \eta \left(\frac{dm}{dt} \right)$$

where $\eta = 0.2$ is the compensated labor supply elasticity, $m = 0.43$ is the marginal tax rate, and $t = 0.31$ is the average tax rate. The tax change is assumed to maintain progressivity, so $dm/dt = m/t = 1.39$. With $dm = 0.01$, this equation yields 21 cents for Browning's (1987) "MEB" as shown. With Stuart's (1984) parameters, $\eta = 0.2$, $m = 0.427$, $t = 0.273$, and $dm/dt = 1.564$, so this equation yields 24 cents.

^cThe text outlines Stuart's (1984) model, but more detail is in his paper. The text also describes why it is not possible to use the same assumptions in the model of Ballard, Shoven, and Whalley (1985).

lar of additional revenue, so his "MEB" is $(CS - dR)/dR$. BSW (1985) use the equivalent variation (EV) of the tax change (in old cum-tax prices), subtract the actual change in revenue, and calculate $(EV - dR)/dR$.³ Browning (1987) also uses the equivalent variation,⁴ but he subtracts the change in revenue along the compensated-labor-supply curve (dR^*). Per dollar of actual additional revenue, his "MEB" is $(EV - dR^*)/dR$.

³They never state this expression explicitly, however, so others misunderstand what was calculated. Triest (1988) assumes that this MEB is measured in pretax prices, when it is actually in prices of the original cum-tax equilibrium. Mayshar (1988b) introduces $EV - dR$ as a "new" measure, not knowing that this is the measure of BSW (1985).

⁴Browning (1987) uses the compensating variation (CV) in his diagram for the other case he considers, but he uses the equivalent variation for the case of interest here, where actual labor supply does not change (see his footnote 24).

It might appear that the measure of BSW (1985) is similar to that of Browning (1987), because both use the equivalent variation, while Stuart (1984) appears to differ by use of the compensating surplus. However, results below show that Stuart's measure is always very close to that of BSW. Indeed, for a truly marginal change in tax and hence in equilibrium prices, the measures of welfare (CS or EV) are equivalent.⁵ Thus, the

⁵The choice of welfare measure is discussed in Peter Diamond and Daniel McFadden (1974), John Kay (1980), Elisha Pazner and Efraim Sadka (1980), Alan Auerbach and Harvey Rosen (1980), and Mayshar (1988b). This choice matters for *total* excess burden, where no-tax prices are very different from cum-tax prices, but not for "*marginal* excess burden." Mayshar (1988b) proves that the EV and CV are equal at the margin, and Eugene Silberberg (1978 pp. 257-9) can be used to show equivalence with the CS measure. For small but discrete changes here, my results confirm Stuart (1984 footnote 5) that "substitution of these alternative measures [EV, CV, or CS] was found to affect the results only at the third significant digit."

FIGURE 1. A CHANGE IN WAGE TAX WITH NO CHANGE IN ACTUAL LABOR

important difference is the revenue figure subtracted (dR or dR^*).

Figure 1 illustrates these definitions for the simple case in which a change in tax leaves actual labor unchanged. The uppermost budget line reflects a fixed gross wage, and the middle budget line reflects an initial proportional wage tax. The consumer chooses point B, and initial revenue is AB. When the wage tax is increased, the consumer chooses point C. The compensating surplus is the amount of the numeraire needed to get back to the old utility, without reoptimizing, the distance from C back to B. Since the actual revenue change is also BC, Stuart's "MEB" is $(BC - BC)/BC = 0$.

EV is the number of dollars taken away at old cum-tax prices that would reduce utility by an amount "equivalent" to the tax, distance BD. Therefore, BSW (1985) measure $(BD - BC)/BC = CD/BC$. This "MEB" may be larger than 0 for a discrete change in Figure 1, but it is 0 for a truly marginal change in tax. It is 0 regardless of the original tax rate or compensated-labor-supply elasticity.

In contrast, Browning (1987) follows Alan Auerbach (1985 p. 72) by subtracting the change in revenue if the consumer were held to the new utility level (dR^*). The new

actual revenue is AC, which equals FH by construction. At the old tax rate, if held to the new utility, the consumer chooses point E. With this labor supply, revenue at the old rate would be GH. Thus, dR^* is the difference, FG, and Browning's "MEB" is $(EG - FG)/BC = EF/BC$. This measure of distortion can be large even if actual labor is unchanged.

Given these large conceptual differences, what are the pros and cons of each definition? Each measure has an appropriate use, but each can easily be misinterpreted. All three papers deal ultimately with the question of whether utility would rise if a marginal increase in the wage tax is used to fund a public project that is separable in utility.⁶ In addressing this question earlier, Atkinson and Stern (1974) isolated two modifications to Paul Samuelson's (1954) rule that the sum of the marginal rates of substitution (ΣMRS) should equal the marginal rate of transformation (MRT). First, if the tax is not lump sum, the "distortionary effect" adds to the relevant costs. Second, in what they call a "revenue effect," changes in after-tax income affect consumer choices and thus affect tax revenue. If leisure is normal, an increased wage tax has an income effect that increases labor, increases revenue from the preexisting tax, and thus makes the project easier to fund. In this case, the "revenue effect" works in the opposite direction as the "distortionary effect."

In the special case in which actual labor does not change, the "distortionary effect" and the "revenue effect" exactly offset each other, so the project increases utility if ΣMRS exceeds the dollar cost of the project. This is the basis for the subsequent

⁶Using Ballard's (1987) terminology, it is a "balanced-budget" analysis. Stuart (1984) also performs a "differential" analysis, in which the additional tax revenue is returned to consumers in a lump sum, but this simulation has no counterpart in BSW (1985) or Browning (1987). Also, Browning (1987) includes a case in which the actual change in labor is the same as the compensated change in labor, but this has no counterpart in Stuart (1984) or BSW (1985). The only case that appears in all three papers is the balanced-budget spending on a separable public good.

finding in the literature that the marginal cost of funds (MCF) is 1.0 when labor does not change.⁷

Since Browning (1987) compares the wage tax to a lump-sum tax, he measures only the distortionary effect. This measure can appropriately be used to compare one tax to another, as it is a correct measure of distortions. However, Browning leaves the incorrect impression that the cost-benefit analyst can use 1 plus his "MEB" as the marginal cost of funds. His measure is not generally enough information to evaluate the public project, because the decision rule should be modified by both the "distortionary effect" and the "revenue effect."⁸

As can be seen from above formulas, Stuart (1984) and BSW (1985) essentially define "marginal excess burden" as the MCF minus 1. With this definition, the cost-benefit analyst can appropriately use $1 + \text{MEB}$ as the MCF. Since the "distortionary effect" and the "revenue effect" exactly offset each other in this special case, however, this "MEB" is zero. Such terminology may leave the incorrect impression that the tax is not distorting. The wage tax is distorting in the usual sense, in that it leaves consumers worse off than a lump-sum tax.

One might think that a lump-sum tax would have no excess burden. Yet for Stuart and BSW, with a preexisting wage tax, a lump-sum increment has "MEB" < 0 . In Figure 2, the initial point B is the same as in Figure 1, but a small lump-sum tax moves the consumer to point C, where the new revenue CG exceeds old revenue FG by the amount CF. Stuart's "MEB" of this lump-sum tax is $(CE - CF)/CF$, which is negative.

FIGURE 2. A LUMP-SUM TAX WITH A PREEXISTING WAGE TAX

The BSW measure is $(CD - CF)/CF$, which also is negative. Browning's "MEB" is $(CD - CD)/CF = 0$. The lump-sum tax has no distortionary effect, but it has a revenue effect because it reduces income and thus causes an increase in labor subject to the preexisting wage tax.

Thus, all three definitions have problems. My own view is that no measure of "marginal excess burden" is necessary. Instead, the marginal cost of funds is enough information. It can be used to compare one tax to another, like Browning's measure, and it can be used to evaluate the public project, like the other two measures. Why define "MEB" as $\text{MCF} - 1$? The marginal cost of funds is the relevant concept in any case, so the cost-benefit analyst must simply add back the 1 subtracted.

II. Comparable Calculations

To calculate his "MEB" in a general equilibrium model, Stuart (1984) first assumes that a representative consumer has an endowment of labor that can be supplied to the market sector or used in production at home. Production in each sector is Cobb-Douglas. Capital stocks are immobile, so labor has a diminishing marginal product

⁷This result is shown in, for example, Stuart (1982), Wildasin (1984), and Triest (1988). Geometrically, in Figure 1, the $\text{MCF} \equiv CS/dR = BC/BC = 1$. Equivalently, $\text{MCF} \equiv EV/dR = BD/BC$, which approaches 1.0 as the tax change becomes small.

⁸This problem is recognized by Browning (personal communication) and discussed by Hansson and Stuart (1988). It does not apply to the other case in Browning (1987), in which the public funds provide benefits that return taxpayers to the original indifference curve, because then the actual change in labor is the compensated change.

in each sector. The consumer uses total income to maximize

$$(1) \quad U = [\alpha(\bar{Y}_1)^{-\rho} + (1-\alpha)(\bar{Y}_2 - \delta)^{-\rho}]^{-1/\rho}$$

where δ is a "minimum required purchase," α is a share parameter, and the elasticity of substitution is $\sigma = 1/(1 + \rho)$. The nonmarket sector has no tax, so labor earns its marginal product, and consumption \bar{Y}_2 equals production Y_2 . In the market sector, labor earns the equilibrium wage times 1 minus the marginal tax rate, and consumption \bar{Y}_1 is less than production Y_1 by the amount of tax paid (the wage bill times the average tax rate). The government spends marginal revenue on the market good.

Stuart (1984) provides detail on the model, and elsewhere (Fullerton, 1989), I further discuss the derivation of parameters and additional steps needed to calculate the other welfare measures. Using Stuart's (1984) model and parameters, I simulate a 1-percent increase in the marginal tax rate, m . Stuart's (1984) measure of "marginal excess burden" is 7 cents, just as in published results. Table 1 shows that the measure of BSW (1985) also rounds to 7 cents. Using the same equilibrium outcome, however, Browning's (1987) measure is 25 cents. Thus, the results differ because the definitions differ.

When labor did not change in Figure 1, Stuart's (1984) measure was shown to provide zero excess burden; so why does he get 7 cents? The reason is that this simulation with a zero uncompensated labor elasticity does not lead to zero change in actual labor supply. Ballard (1987) points out that this change in the progressive tax structure effectively changes the "virtual" income of the consumer. The change in the net wage by itself would not change labor supply, but the change in virtual income does. The condition for the marginal cost of funds to be 1.0 is not that the uncompensated elasticity is zero, but that actual labor does not change. Thus, Stuart's (1984) "MEB" ($= \text{MCF} - 1$) will not be zero whenever any aspect of the reform causes a response in the quantity of labor.

To set his parameters, Stuart (1984) differentiates labor supply with respect to the net wage and imposes an uncompensated elasticity of 0, a compensated elasticity of 0.2, and an initial MRS of 1. Together with his data, these three conditions determine the three parameters (δ , α , and ρ). This procedure is consistent with the definition of an elasticity, since the differentiation varies only the net wage. As an alternative, I search a three-dimensional grid for values of δ , α , and ρ where the compensated elasticity is still 0.2 and the MRS is 1, but where actual labor does not change in this particular simulation. In this case, Table 1 shows that Stuart's "MEB" is zero.⁹

Using these new parameters, the measure of BSW also is zero; so why do they get 12 cents? As pointed out by Ballard (1987), they have other taxes that introduce second-best effects. The simulation here demonstrates that their definition would yield a zero "marginal excess burden" in the case with no other taxes and an unchanged equilibrium supply of labor.¹⁰

The model of BSW (1985) is not used here to calculate the three measures. One reason is that this model has 12 different consumer groups with different marginal tax rates and elasticities. Another reason is that the calculation of dR^* would be extremely difficult with many tax instruments. It would require the compensated demand for each commodity, the sales tax on each compensated quantity, and all factor taxes on producers at those quantities.

Finally, I impose on Stuart's (1984) model the condition that production is linear, so the gross wage is constant in general equi-

⁹These new parameters are not preferred to those of Stuart (1984). Indeed, they imply that the uncompensated elasticity is (slightly) negative. They are used here only to illustrate the important conceptual point that Stuart's measure is zero when actual labor does not change. This point was not clear in Stuart's (1984) paper.

¹⁰The point of this note does not arise when their model is used in a revenue-neutral reform, as in every previous application, because the EV measures the change in welfare with no subtraction for any change in revenue.

librium. Stuart's model then reduces exactly to Browning's (1987) model (where the wage was constant by assumption). An additional grid search is performed to impose the three conditions discussed above (the compensated labor supply elasticity is 0.2, the initial MRS is 1, and actual labor is unchanged in this simulation). Table 1 shows that Browning's "MEB" is 24 cents, while the other measures are zero. Browning's fixed wage therefore raises his own "MEB" by 20 percent (24 cents vs. 20 cents), relative to a comparable model with a varying wage.

III. Conclusion

With only the "distortionary effect," Browning's (1987) "marginal excess burden" is a familiar concept. It is the marginal analogue of total excess burden, defined as the welfare difference between a distorting tax and a lump-sum tax. However, it is not enough information to set public spending. With the addition of the "revenue effect," the measure of Stuart (1984) or of BSW (1985) does provide enough information to decide on a project that is separable in utility. However, it can be zero for a distorting tax. It is defined as the marginal cost of funds minus 1, but there is no need for a concept other than the MCF itself.

The marginal cost of funds can be used to compare the distorting effects of two different tax changes, because the marginal dollar always has the same revenue effect. For a given tax, the MCF can be compared to the benefits of a public project. In general, the MCF does depend on elasticities and tax rates in the model. If the project is not separable in utility, it also depends on the assumed effect of the public project on labor supply. For a marginal dollar of revenue, however, it does not depend on the definition of consumer welfare.

Does Student Aid Affect College Enrollment? New Evidence on a Persistent Controversy

By MICHAEL S. MCPHERSON AND MORTON OWEN SCHAPIRO*

Certainly no aspect of the evaluation of federal student aid has attracted more attention than the question of its impact on enrollment levels and patterns. Although it is important to note that affecting enrollment is not the whole justification for student aid, the aim of promoting the enrollment of less-affluent students has been central to the case for federal student aid throughout its history.¹ Despite quite substantial empirical efforts, the issue of the size—and even the existence—of these enrollment effects remains unsettled. A major difficulty is that controlled econometric studies of student behavior, the best of which have relied on cross-sectional data on individuals, lead us to expect substantial effects of student aid, but these effects have been hard to discern in the historical time series.

Before the introduction of the Basic Educational Opportunity Grant program in 1974 (later renamed Pell), total federal spending on need-based grants to undergraduate students amounted to less than a third of a billion in 1982 dollars and accounted for less than 3 percent of total tuition revenue. By 1980, need-based federal grants were over 3.5 billion 1982 dollars, and the Pell program accounted for more than 80 per-

cent of that total. These federal grants to students amounted to 29 percent of total tuition revenue of U.S. colleges and universities in 1980. Over the same period, federally subsidized loans for college grew from around \$3 billion to over \$5.5 billion 1982 dollars. Yet, despite this dramatic change in financing, enrollment rates in 1980 were, if anything, slightly below those earlier in the decade. After 1980, the grant programs experienced little real growth, subsidized loans continued to increase, and enrollment rates remained fairly steady.² The relative stability of overall enrollment rates in the light of substantial fluctuations in federal spending on student aid is an empirical puzzle and a challenge for public policy.

This paper reports on a disaggregated econometric analysis of time-series evidence on U.S. higher-education enrollments and net costs over the 1974–1984 period. Section I contains a brief literature review. Section II presents our regression results and compares them to findings from cross-sectional studies. Section III contains a summary and conclusions.

I. The Literature

A great many studies over the years have attempted to estimate the impact of price or net cost of education on students' postsecondary education decisions.³ A minority of

¹A broader framework of goals for federal student aid is suggested in McPherson (1988).

²More-detailed examination of the federal student aid programs and their changing funding levels is provided in McPherson and Schapiro (1990). Enrollment data are from the Bureau of Labor Statistics, Current Population Survey. Student aid data are from Donald Gillespie and Nancy Carlson (1983) and Gwendolyn Lewis (1988).

³A number of able surveys of this literature exist. A recent one, which provides references to many of its predecessors, is Larry Leslie and Paul Brinkman (1987); see also Leslie and Brinkman (1988).

those studies have tried to measure specifically the effect of student aid on enrollment decisions, with the rest focusing on the impact of tuition price. Although the studies differ widely in data sources and estimation techniques, they tend to agree on two main points. First, student decisions to enroll in college respond positively and nontrivially to price cuts or aid increases. Second, decisions about where to attend school also respond nontrivially to changes in the relative prices of schooling alternatives.

Perhaps the best and most influential of these studies is Charles Manski and David Wise (1983). According to a simulation based on their estimates of college choices of a sample of 1972 high school graduates, the Pell grant program as it existed in 1979–1980 should have left enrollments 21 percent higher than they would have been without Pell, with the increases heavily concentrated at two-year colleges and among students from lower-income families. The predicted response by income group varies greatly: there is a 59-percent enrollment increase for low-income students, a 12-percent increase for middle-income students, and only a 3-percent increase for upper-income students.⁴

Further econometric support for the claim that financial aid influences enrollment is provided by the many studies that estimate the effect of tuition variations on enrollment behavior. Although changes in grant awards may have somewhat different effects

on enrollments from tuition changes that have equivalent impacts on net price, the size of those effects and their variation across income classes should be similar. It is therefore reassuring to note that most studies of enrollment demand find significant positive effects of tuition reductions on enrollment levels and find that the enrollment effects (in percentage terms) are larger for lower-income students.⁵ Leslie and Brinkman (1987) find that a consensus of the studies they survey puts the effects of a price cut of \$100 (1982–1983 academic-year dollars) on national enrollment of 18–24 year-olds at about 1.8 percent. On the assumption that a price cut and a grant increase of the same magnitude have equal effects, the Pell program as it existed in 1979 should have boosted total enrollment by approximately 10–15 percent, compared to what enrollments would have been in that year without the program.⁶ This is roughly comparable to the findings of studies like Manski and Wise (1983) that try to measure the effect of grant aid directly.

These econometric findings create an expectation that it should be possible to detect effects of changing student-aid policy in the national time-series data. However, a number of observers have noted the absence of any obvious change in national enrollment trends in response to changes in federal student-aid policies and funding levels, (e.g., Robert Zemsky [1988] and Leslie and Brinkman [1988]). Moreover, some of the most careful econometric studies (in-

⁴Several key features of the Manski and Wise (1983) findings on the access effects of Pell grants are corroborated by other studies. Estimates developed by Leslie and Brinkman (1988) from their analysis of seven econometric studies (including that of Manski and Wise) suggest that the Pell program as it existed at the end of the 1970's should have raised lower-income enrollment by between 20 percent and 40 percent, implying an increase in total enrollment of approximately 10–20 percent. They point out that these results indicate that roughly between 500,000 and 1 million low-income students and approximately 400,000 middle-income students are enrolled in college because of grant aid. The midpoint of the total of these figures is slightly over 1 million students, approximately 16 percent of all full-time students. For more detailed discussion of the relevant literature, see McPherson and Schapiro (1990).

⁵See Leslie and Brinkman (1987) for a comprehensive survey. For an analytically oriented survey that examines the relation between income levels and price responsiveness of enrollment, see McPherson (1978).

⁶This assumes an average Pell award of about \$1,000 1979 dollars per recipient and that about half of freshmen should have been eligible for Pell awards under 1979 rules. Actual enrollment rates of high school graduates grew by about 5 percent from 1973 to 1979. Thus, these estimates imply that, in the absence of the Pell program, the enrollment rate would have fallen by between 5 percent and 10 percent over this time period. One potential explanation for such a decline is the sharp drop in the earnings differential between college and high school graduates over this period. See Lawrence Katz and Kevin Murphy (1990).

cluding Manski and Wise [1983]) rely on data collected before the introduction of the Pell program in 1974. Inferences from these estimates to behavior in the post-Pell period may be suspect if the introduction of a major new federal program changed the structure of the aid-enrollment relationship.

W. Lee Hansen (1983), in a highly influential study, has suggested that it is useful to look at relative enrollment rates of more- and less-affluent students in gauging the impact of federal student aid, on the grounds that changes over time in federal student aid are the most obvious factor that should affect time-series changes in the enrollment behavior of these two groups differentially. He used Current Population Survey (CPS) data in examining enrollment rates for students from families with dependents aged 18-24 for two time periods: 1971-1972 and 1978-1979. He then calculated the ratio of the enrollment rates of below- to above-median-income families in the two periods and found that the ratios declined for whites, blacks, men, and women. When a weighted average was taken for whites and blacks and for men and women, the ratios again fell between the two periods.

The conclusion from this study is well known among researchers and policy makers: "These data force one to conclude that the greater availability of student financial aid, targeted largely toward students from below-median-income families, did little, if anything, to increase access. The results certainly do not accord with expectations that access would increase for lower-income dependents relative to higher-income dependents." (Hansen, 1983 p. 93)

There are some obvious limitations in interpreting this kind of snapshot comparison at two points in time. First, year-to-year fluctuations may obscure underlying trends, so that increasing the number of years in the comparison is helpful. Second, controlling for variation in other factors that affect the demand for enrollment is not possible with this method. Such factors as overall economic conditions, changes in rates of return to higher education, and changes in

opportunity costs of college enrollment (as produced, for example, by changes in the draft law) may influence the comparison if these factors affect different income groups differently. Finally, this kind of comparison is not responsive to changes over time in the targeting of student aid. During the 1970's, the total amount of federal student aid not only increased substantially, but also changed significantly in its distribution. A larger fraction of available aid was targeted at middle- and upper-income students in the late 1970's, tending to obscure any effect on differential enrollment rates that might have occurred.

II. Analysis

Summarizing the above discussion, researchers have found significant econometric evidence of a rather large enrollment response to differences in student aid. However, despite substantial variation in aid over time, enrollment responses are not readily detected in national time-series data. Earlier analysts have, however, failed to subject time-series data from the post-Pell era to econometric analysis.⁷

Our analysis is based on enrollment, tuition, and financial-aid data for population subgroups over the 1974-1984 period. The enrollment data are from the Current Population Survey; the tuition and financial aid data are from an annual survey of college freshmen, The American Freshman survey.⁸

⁷Several time-series econometric studies of enrollment demand exist, but these predate the introduction of the Basic Grants program. See John Hight (1975), Robert Campbell and Barry Siegel (1967), and Stephen Hoenack and William Weiler (1975). Results from these studies are, on the whole, comparable to the findings of cross-sectional econometric studies.

⁸The data on tuition, student aid, and income in the American Freshman Survey are self-reported by students. No doubt this self-reporting introduces measurement error in these variables. Nevertheless, we use these data for several reasons. First, they are the only consistently reported annual data on net costs and income. Second, there is no reason to expect the biases in student reporting of income and costs to vary systematically over time. Hence, while the data may be inaccurate as estimates of these values in any particular year, their variation over time should be more

TABLE 1—DESCRIPTIVE STATISTICS

Statistic	N	Mean	SD	Minimum	Maximum
All institutions:					
Enrollment rate	66	0.427	0.117	0.246	0.672
Net cost (NETCOST)	66	3.056	0.693	1.974	4.623
Private institutions:					
Enrollment rate	60	0.111	0.051	0.037	0.228
Net cost (NETCSTPR)	60	4.126	0.949	2.622	6.336
Public institutions:					
Enrollment rate	60	0.318	0.070	0.194	0.461
Net cost (NETCSTPU)	60	2.460	0.433	1.657	3.197

Note: Net costs are reported in thousands of dollars.

The individual data points in our regressions are an enrollment rate and an average net cost for a particular population subgroup (e.g., white women, incomes below \$10,000) in a particular year.⁹ We employ three such data sets: one for public institutions, one for private institutions, and one that averages over public and private institutions. Investigations with the data suggest that small samples in the CPS data for blacks and other races preclude time-series analysis at the level of disaggregation we employ. Therefore, the results we report here are limited to whites only. In the regressions that report on enrollments at public and private institutions separately, we are forced to exclude data for 1980, because mistakes made by the Bureau of the Census in coding the 1980 CPS make it impossible to distinguish public from private enroll-

ment. Thus, regressions using the combined data set are based on 66 observations (three income groups, two genders, and 11 years). Regressions for public and for private institutions have 60 observations (three income groups, two genders, and 10 years). Table 1 contains descriptive statistics.

Table 2 presents regression results in which enrollment rates averaged across public and private institutions are explained by time-series changes in net cost and other variables. Given the nature of the data set, heteroskedasticity is a natural worry. Therefore, for all of the regression results that follow, estimated asymptotic covariance matrices were computed under the assumption of heteroskedasticity in order to calculate the standard errors.¹⁰ These adjusted standard errors were used in all tests of significance. The regression equation includes a time trend along with a dummy variable for gender (FEMALE: 1 for females and 0 for males) and dummy variables for the medium-income group (MED: income between \$10,000 and \$30,000 in 1978 dollars) and for the high-income group (HIGH: income over \$30,000). In addition, the equation includes terms that interact income with the net-cost variable, the gender dummy, and the time trend (TIME).

reliable. Finally, we know of no reason why any systematic biases in these variables should be correlated with variations in the dependent variable (the enrollment rate). Note that the dependent variable is obtained from a data set that is collected separately from these independent variables.

⁹We define "net cost" as the difference between tuition (the "sticker price") and the subsidy value of student aid. Net cost is measured in thousands of 1978–1979 dollars. The subsidy value is calculated on the assumption that subsidized loans obtained by students from the federal government provide a 50-percent subsidy. Several attempts to estimate the present value of student-loan repayment streams put the implicit subsidy at approximately half the face value of the loan. See Barry Bosworth et al. (1987) and Arthur Hauptman (1985).

¹⁰For the derivation of this technique, see Halbert White (1980). The correction of the standard errors does not produce major changes from the results obtained without the correction.

Notes: $N = 66$; mean enrollment rate = 0.427; root MSE = 0.023; CV = 5.3; $R^2 = 0.97$; adjusted $R^2 = 0.96$.

^aSignificant at $P < 0.10$ level; *significant at $P < 0.05$ level; **significant at $P < 0.01$ level.

NETCSTHI interacts NETCOST with the dummy variable representing high income. NETCSTMED interacts NETCOST with the medium-income dummy variable. TIMEHI and TIMEMED interact TIME with the income dummies, while FEMHI and FEMMED interact FEMALE with the income dummies.

We have the following expectations about the signs of the coefficients. The NETCOST coefficient, which measures the responsiveness of enrollment to net cost for the low-income group, should be negative. The coefficient on NETCSTMED measures the difference between the responsiveness of low- and middle-income students' enrollment to changes in net cost. Cross-sectional studies generally indicate that higher-income students are less responsive to price than are lower-income students. We therefore expect the coefficient on NETCSTMED to be positive, muting the negative effect of net cost on enrollment relative to that of lower-income students. For the same

reason, we expect the coefficient on NETCSTHI to be positive (and larger than that on NETCSTMED).

As Table 2 shows, all the estimated coefficients on these net-cost variables are significant with the expected sign.¹¹ Increases in net cost lead to lower enrollment for the low-income group, and the interaction effects are positive and significant, showing that this effect is smaller for middle- and upper-income students. In fact, the coefficients on the net-cost \times income interaction terms are larger in absolute value than the

¹¹In order to ensure that all predicted values lie within the unit interval, we ran regressions using a logistic transformation of the dependent variable. These results did not differ substantively from those reported below. Further, an examination of the residuals from the regressions we present below did not provide any evidence of autocorrelation within particular economic or demographic groups. (Note that standard tests for autocorrelation are inappropriate, given the panel nature of the data set.)

coefficient on net cost, implying that the predicted effect of net cost on enrollment in this equation is positive (and statistically significant, as the chi-square tests show) for middle- and upper-income students.¹² It is possible that this unexpected result for more-affluent students is explained by a supply, rather than a demand, effect: a positive relationship between enrollment and net cost may come about because (particularly in the 1980's) a strong demand among middle- and upper-income students for higher education has caused colleges and universities to raise their prices.¹³

The negative coefficient on net cost implies that for lower-income students a \$100 net-cost increase results in an enrollment decline of about 0.68 percentage points, which is about a 2.2-percent decline. We noted above that Leslie and Brinkman (1987) find a consensus in the literature that a \$100 increase in net cost reduces enrollment rates by 1.8 percent. Converting our estimates in 1978–1979 dollars to the 1982–1983 equivalent relied on by Leslie and Brinkman (1987), we find that a \$100 cost increase results in a 1.6-percent enrollment decline for low-income students. The Leslie and Brinkman (1987) figure is in effect averaged over all income groups. As noted earlier, most studies find higher price responsiveness among lower-income students. Manski and Wise's (1983) results, for

example, suggest that a \$100 net-cost increase for low-income students (in 1979 dollars) leads to a 4.9-percent decline in enrollment.¹⁴ The result here, while lower than the estimate of Manski and Wise, seems broadly consistent with typical cross-sectional findings. The important point is that our econometrically controlled time-series analysis supports the view that changes in costs lead to changes in enrollment for low-income students.

We turn next to the coefficients relating to gender and to the time trend. The coefficient on the FEMALE variable indicates that, over the 1974–1984 period, the enrollment rate for women tended to be about 5 percentage points higher than that for men. The fact that the variables interacting FEMALE with income are close to zero and statistically nonsignificant indicates that this gender effect is constant across income groups (chi-square values show that the net effect of the FEMALE variable on enrollment is positive and significant for all three income groups). The time trend is negative and significant for the low-income group, suggesting a tendency for the enrollment propensity for that group to fall over time, but the coefficient is quite small, with the estimated rate of decline being just 0.36 percentage points per year. There is no significant time trend for middle-income students, but there is a significant negative time trend of 0.66 percentage points per year for high-income students. The negative time trends noted here and below may indicate the presence of unmeasured variables tending to lower enrollment propensities over time.

Tables 3 and 4 examine private enrollment and public enrollment separately. This breakdown is particularly important because of a potential problem with the endogeneity of the price variable in the equations that average over sectors: if, for example, the number of students choosing to attend private institutions (which are generally higher priced) rises, this choice

¹²The values of the intercept and the MED and HIGH dummies imply that for all three income groups the intercept terms are positive but are a declining function of income. This may seem surprising, since we expect enrollment rates to vary positively with income. However, the presence of a negative net cost effect for the low-income group, coupled with positive effects for the other income groups, implies that predicted levels of enrollment evaluated at means in fact increase with income.

¹³Because enrollment rates are substantially higher for middle- and high-income students than for low-income students and because these students generally pay higher net costs than do low-income students, it is more plausible to expect a supply response to the behavior of middle- and high-income students than to that of the low-income group. Ideally, we could test this conjecture about supply-side effects by including demand-shift variables in a multiequation analysis; this is, however, beyond the scope of the present study.

¹⁴This coefficient is computed from information in Manski and Wise's (1983) tables 7.2 and 7.4.

will be reflected in higher average net cost. Distinguishing between sectors does not completely eliminate this problem, since there is price variation within each sector, but it reduces the problem substantially. The structure of the equations is similar to that in Table 2, which combines public and private enrollment, except that the net-cost variables (NETCSTPU and NETCSTPR, respectively) and the net-cost \times income interaction terms (NTCSTMPU and NTCSTHPU for public middle- and high-incomes and NTCSTMPR and NTCSTHPR for private middle- and high-incomes) are specific to the sector whose enrollment is being explained. It would be natural to test for the significance of variables measuring cross-price effects. Unfortunately, a high correlation between the time series for public and private net costs (on the order of 90 percent) makes it impossible to include both variables in the same equation.

As in the combined equation, all the coefficients in the private and public equations that are significant have the expected sign.¹⁵ For private enrollment, we estimate that a \$100 increase in net cost lowers enrollment by about 6.0 percent for low-income students. In the private-institution equation, the net-cost \times middle-income interaction is positive and significant, implying that the price responsiveness of students from middle-income families is significantly lower than that of students from low-income families. The overall net effect of cost on private enrollment for middle-income families is negative and significant, indicating that, as for low-income students, rises in net cost reduce enrollment for middle-income students. The net-cost \times income interaction

variable for students from high-income families is also positive and significant, indicating that they are less responsive to price. However, the overall net effect of cost increases on high-income private enrollment is not significantly different from zero.

Continuing with the results for private enrollment in Table 3, we find that low-income women have a significantly higher enrollment propensity than low-income men. Moreover, chi-square values indicate that enrollment propensities in private colleges are also significantly higher for middle-income and high-income women than for men of the same income class. We find a 0.34-percentage-point negative and significant time trend for high-income students. The time trends for the low- and middle-income groups are not statistically significant.

Turning to the results for public enrollment in Table 4, we find that the coefficient on net cost for low-income students has the expected negative sign but is not statistically significant at conventional levels. (The point estimate would imply that a \$100 increase in net cost reduces enrollment at public institutions by about 1.6 percent for low-income students.) As expected, the coefficients on the net-cost \times income interactions are both positive and significant. For both middle- and high-income groups, chi-square values indicate that the net effect of cost on enrollment is positive and statistically significant. Again, the FEMALE variable was positive and statistically significant for each income group. The only significant time trend is a small negative one (-0.36 percentage points per year) for low-income students.¹⁶

¹⁵The relative size of the coefficients in the public and private equations may also be of interest. Even taking student aid into account, low-income students on average face higher prices in private institutions. If this implies that private higher education is viewed as a "luxury" by low-income families, then low-income students might be expected to be more sensitive to changes in the price at private than at public institutions. However, we do not find a statistically significant difference between the net-cost coefficients for the two sectors in our sample.

¹⁶In a further refinement of the analysis, we break down net cost into its two components: the published tuition (or sticker price) and the subsidy value of aid (AID). (These results are discussed in detail in McPherson and Schapiro [1990]). This step serves the purposes, first, of shedding light on the relative magnitudes of the aid and sticker-price effects and, second, of pushing the data to see if anomalies or inconsistencies surface. When public and private institutions are combined, the two variables have the expected sign: a higher sticker price lowers enrollment, and more aid raises enrollment. The sticker-price coefficient is statistically significant, but the AID coefficient is not significant at the 10-percent level. As for the magnitudes,

III. Summary and Conclusions

Our most important and reliable finding is that increases in the net cost of attendance have a negative and statistically significant effect on enrollment for white students from low-income families. Moreover, the magnitude of this net-cost effect is reasonable in light of that found in earlier econometric studies of enrollment demand. These results hold for a combined sample of public and private institutions as well as for a subsample limited to private institutions.¹⁷ (For the public sample, the sign was as expected but not significant.) It is not possible to use our data set to test for net-cost effects for blacks or other racial-ethnic groups because of excessive sampling variation in the estimated enrollment rates for these students.

Our finding that the time-series and cross-sectional results for low-income white students are consistent is an important first step in resolving a long-standing controversy in the literature.¹⁸ These results derive from

the absolute values of the two coefficients are not statistically different from each other. When public and private enrollment are considered separately, we find that for low-income students at private institutions, AID has the expected positive sign and is statistically significant; sticker price has the expected negative sign, and is also statistically significant; and again, the coefficients do not differ significantly from each other. For low-income students at public institutions, the two signs are as expected but are not statistically significant.

¹⁷When net cost is broken down into its two components, tuition and subsidy value of aid, the results generally continue to support the finding that the enrollment decisions of low-income students are sensitive to the costs they face.

¹⁸A referee raised the interesting point that the post-1980 behavior of several important variables influencing enrollment differed substantially from their behavior before 1981. In particular, tuition rose quite rapidly after 1980, and the growth of federal student aid slowed substantially. Might the difference between our results and those of Hansen (1983) simply result from our inclusion of post-1980 data that did not exist at the time of Hansen's study? We examined this possibility by estimating our equations for the 1974–1980 time period. The results were essentially quite similar to those for the full period, although some of the coefficients were less precisely estimated. An attempt to obtain estimates for the 1981–1984 period was unsuccessful, an outcome we attribute to the severe limitation imposed by the degrees of freedom.

the fact that we have systematically related changes in net cost to changes in enrollment and have not simply looked at enrollment levels at two points in time. It is important to appreciate that these findings for low-income students would be obscured in an analysis that aggregated over income groups, since our evidence suggests (in line with the findings of cross-sectional studies) that the behavior of these income groups is quite different.

We found a very different picture when we looked at the behavior of more-affluent students. We found no evidence in these data that increases in net cost inhibited enrollment in these income groups. In fact, for the upper-income group, there was a fairly consistent positive effect of net cost on enrollment, which may be interpreted as indicating a tendency for high enrollment demand among affluent students to lead to higher net costs for those students. For middle-income students, we found that net cost did not have a consistent effect on enrollment in our equations.

The above analysis indicates that changes in the net price facing lower-income students have significant effects on their enrollment behavior. An important policy issue, however, is whether changes in federal aid in fact wind up changing net cost. If, for example, increases in federal aid led to decreases in the amount of aid awarded by institutions or to increases in tuition, the effect of aid on net cost would be muted. This issue deserves more systematic treatment than we can give it here. However, findings from a study of the effects of student aid on institutions (McPherson et al., 1989; McPherson and Schapiro, 1991) suggest that these potential offsetting effects may not be empirically important. The time-series evidence on net cost further suggests that periods when federal aid is generous coincide with periods when the net cost facing low-income students is lower. This supports the view that these potential offsets are not important factors.

In sum, a more careful analysis of the historical data has raised serious doubts about the hypothesis that federal student aid has failed to affect enrollment patterns in U.S. higher education significantly over

the past two decades. Our assessment indicates that time-series evidence on the enrollment behavior of low-income white students is quite consistent with the many cross-sectional estimates of aid effects in the literature. While further analysis seems warranted, it is nonetheless clear that policymakers must carefully consider potential enrollment effects when determining aid policy.

Are Workers Permanently Scarred by Job Displacements?

By CHRISTOPHER J. RUHM*

This paper investigates whether workers suffer lasting "scars" following job displacements. Using David T. Ellwood's (1982) terminology, "scars" represent persistent effects, whereas "blemishes" are transitory adjustments which dissipate over time. More precisely, dislocated individuals are defined as scarred if they continue to earn less or to be unemployed more than their nondisplaced counterparts, even after the conclusion of a several-year adjustment period.

Displacements may have a transitory impact if workers initially obtain unstable positions but later move to more secure jobs or if low wages are received during short-lasting probationary or training periods. These temporary effects, although important, cause less concern than persistent scarring. It is therefore somewhat surprising that, despite the proliferation of recent research studying the consequences of permanent layoffs, relatively little is known about the duration of the associated adjustment problems.¹

Data for this study were obtained for heads of households from the 1969–1982 waves (survey reporting years) of the *Michigan Panel Study of Income Dynamics* (PSID). Displacement status was ascertained for the five base years 1971–1975, with respondents defined as permanently displaced if they terminated jobs as the result of plant closings or layoffs (excluding departures from temporary or seasonal jobs) and failed to return to the original employer by the end of the second full calendar year

following the layoff. Data were collected on unemployment and weekly wages for the three years preceding and four years following the base period. The base year is hereafter referred to as time t , the following four years are referred to as periods $t+1$ through $t+4$, and numbers subtracted from t refer to periods preceding the base year. Information was also assembled indicating whether respondents were displaced in year $t+5$.

The sample includes household heads between the ages of 21 and 65 at time t who participated in the labor force during some part of each of years t through $t+5$ and received positive earnings at some time during period $t-2$ or $t-3$. The analysis is therefore restricted to individuals with fairly strong attachments to the labor force.² To reduce the number of multiple observations for given individuals, data were used only for base years in which the individual was displaced and for a maximum of one randomly chosen base year in which no displacement occurred.³ The sample contains 3,813 person-year observations, 800 for workers losing jobs at time 0 and 3,013 for individuals not displaced during that year.

²The PSID oversamples low-income individuals and has information on relatively few permanent job changers (even with pooling). This raises concern that the results of this study might differ from those obtained using more-representative data. For this reason, regression estimates of postdisplacement unemployment on a commonly defined set of control variables were compared for the PSID and for household heads in the *Displaced Workers Survey*, a supplement to the January 1984 *Current Population Survey*. Coefficients from the two sets of regressions were similar, suggesting that the findings of this paper are reasonably robust.

³The precise selection criteria were as follows: a random variable V was created which, for each individual, had an equal probability of taking integer values $1 \leq V \leq 5$; the base year was then included in the sample if: 1) $\text{YEAR} - 1970 - V = 0$; or 2) if a permanent displacement occurred either at t or $t+5$.

*Assistant Professor, Department of Economics, Boston University. I thank Peter Doeringer, Daniel Hamermesh, and Lori Kletzer for helpful comments on earlier versions of this paper. Funding was received from the U.S. Department of Labor, Bureau of International Labor Affairs. The usual disclaimer applies.

¹See the survey article by Daniel S. Hamermesh (1989) and the edited volume by John T. Addison (1990) for examples of recent work.

I. Estimation Technique

The effect of displacements occurring at time t on employment conditions at $t+n$ can be estimated from regressions of

$$(1) \quad Y_{i,t+n} = \mathbf{X}_{i,t}\alpha + D_{i,t}\beta + \mu_{i,t+n}$$

where i is an individual subscript, Y is the dependent variable (either weeks of unemployment or the natural log of weekly wages), \mathbf{X} is a vector of observable characteristics, D is a dummy variable indicating whether a displacement occurs at time t , and μ is the regression disturbance term. These estimates will be biased, however, if the vector of independent variables fails to control fully for all types of heterogeneity that jointly influence the dependent variable and the probability of displacement. For this reason, two additional specifications were estimated.

In the first, predisplacement wages and predisplacement unemployment ($Y_{i,t-m}$) were included to control for heterogeneity not captured by \mathbf{X} , yielding the regression equation

$$(2) \quad Y_{i,t+n} = \mathbf{X}_{i,t}\alpha + D_{i,t}\beta + Y_{i,t-m}\gamma + \mu_{i,t+n}$$

The second specification included persons involuntarily terminating jobs in year 5 (after the end of the observation period) as a comparison group. These equations were of the form

$$(3) \quad Y_{i,t+n} = \mathbf{X}_{i,t}\alpha + D_{i,t}\beta + D_{i,t+5}\delta + \mu_{i,t+n}$$

with the bias introduced by unobserved heterogeneity captured by the $\hat{\delta}$. The net displacement effect was then calculated as $\hat{\beta} - \hat{\delta}$, where $\hat{\delta}$ is the average value of $\hat{\delta}$ for periods t through $t+2$.⁴ The earnings re-

gressions were estimated using ordinary least squares, and the unemployment equations were estimated as TOBIT models.

There is some ambiguity as to the appropriate choice of lagged dependent variables to be used in equation (2). If a period shortly before the involuntary termination is chosen (e.g., Y_{t-1}) and employment conditions begin to deteriorate prior to permanent separations (as firms institute temporary layoffs or obtain wage concessions), the coefficient on the lagged dependent variable will include a portion of the displacement effect, and $\hat{\beta}$ will understate the impact of permanent layoffs. Conversely, the use of a longer lag period will cause $\hat{\beta}$ to overstate the actual displacement effect if firms strategically terminate workers whose performance has been deteriorating or who previously received high pay, relative to their productivity. This occurs because the displacement coefficient captures the effects of changes that would have been expected even in the absence of mobility.⁵

Preliminary analysis of the comparison group of workers displaced in year $t+5$ revealed that wage and employment adjustments begin two calendar years before permanent layoffs. For this reason, equation (2) was estimated with the dependent variable alternatively lagged one and three periods prior to the base year. Regressions with Y_{t-1} (Y_{t-3}) included are likely to provide lower (upper) bounds on the actual displacement effect.

II. Wage Scars and Unemployment Blemishes

Permanent layoffs are associated with substantially elevated initial unemployment. Between years t and $t+2$, dislocated workers were three times more likely than their counterparts to experience some unemployment (83.2 percent vs. 26.3 percent), aver-

⁴As discussed in the next paragraph, $\hat{\delta}$ will include a portion of the displacement effect in later years, if adjustments begin prior to the job termination. Jacob Mincer (1986) and I (Ruhm, 1990) have previously used subsequent job losers as a comparison group to account for unobserved differences when analyzing the effects of job mobility

⁵Closely analogous concerns are raised in the econometric analysis of training programs, where reductions in employment and earnings are typically observed shortly prior to the beginning of the training period. See Orley Ashenfelter (1978), Ashenfelter and David Card (1985), and Card and Daniel Sullivan (1988) for discussions of these issues.

TABLE 1—POSTDISPLACEMENT WAGE AND UNEMPLOYMENT DIFFERENTIALS

Time period	Unemployment				Weekly wages			
	a	b	c	d	a	b	c	d
t	8.35 (27.28)	8.43 (27.22)	7.10 (25.94)	8.73 (26.99)	-0.1058 (5.39)	-0.1054 (6.49)	-0.0645 (4.64)	-0.1149 (5.73)
$t + 1$	4.32 (17.27)	4.18 (17.15)	3.69 (15.53)	4.64 (19.98)	-0.1751 (8.73)	-0.1664 (9.89)	-0.1365 (9.09)	-0.1820 (8.88)
$t + 2$	2.08 (9.45)	2.11 (9.21)	1.79 (8.29)	2.24 (9.65)	-0.1623 (7.77)	-0.1585 (8.83)	-0.1188 (7.25)	-0.1690 (7.91)
$t + 3$	1.45 (7.00)	1.40 (6.83)	1.16 (5.84)	1.77 (8.07)	-0.1486 (7.67)	-0.1435 (8.03)	-0.1067 (6.43)	-0.1627 (7.17)
$t + 4$	1.27 (5.81)	1.12 (5.62)	0.88 (4.60)	1.85 (8.56)	-0.1473 (6.84)	-0.1402 (7.34)	-0.1117 (6.33)	-0.1698 (7.73)
Control for heterogeneity:	none	Y_{t-3}	Y_{t-1}	D_{t+5}	none	Y_{t-3}	Y_{t-1}	D_{t+5}
				0.86 (2.61)				-0.0434 (1.77)

Notes: See text for explanation of columns a–d. Unemployment equations are estimated using maximum-likelihood TOBIT methods; the wage equations are estimated by ordinary least squares. The unemployment coefficients show the impact of marginal changes in the regressors on actual joblessness and are obtained by evaluating the TOBIT regressions at the independent variable means. The wage coefficients show the impact of base-year displacements on the natural log of weekly wages. Numbers in parentheses are t statistics. Regressions include controls for experience, education, marital status, race, sex, city size, tenure, the survey year, industry, occupation, and age (> 55 years old). Coefficient on D_{t+5} is the average obtained from regressions for years t through $t + 2$.

aged six times as many weeks out of work (23.9 vs. 3.8 weeks), were eight times more probable to be unemployed for more than six months (35.8 percent vs. 4.5 percent), and were jobless for more than one year 16 times as frequently (12.9 percent vs. 0.8 percent).

Dislocated workers were also more than twice as likely to experience wage reductions exceeding 25 percent between $t - 2$ and $t + 2$ (28.6 percent vs. 14.1 percent), and lost more than 10 percent of previous wages 1.6 times as often (40.1 percent vs. 25.0 percent). Although displaced individuals averaged only a 1.5-percent earnings reduction over the four years, they missed out entirely on the 8.4-percent real wage gain obtained by the control group over the same period.

I now turn to considering whether displacements leave lasting scars. Table 1 displays regression results of unemployment

and wage equations estimated for periods t through $t + 4$. For each dependent variable, coefficients in column a are obtained from estimating equation (1), which includes no controls for unobserved heterogeneity. Coefficient in columns b and c are from equation (2) with Y_{t-3} and Y_{t-1} , respectively, incorporated.⁶ Estimates in column d are from equation (3), with the final entry in the column indicating δ . In this case, the effects of base-year layoffs are calculated by subtracting δ from the estimated coefficients on D_t . Displacement impacts in the early years (t through $t + 2$) indicate adjustment costs in the periods immediately following permanent job loss. The major focus of this paper, however, is on longer-run effects, as

⁶If data for period $t - 3$ were unavailable (in Table 1, column b), corresponding information for period $t - 2$ was used.

measured by the coefficients for years $t+3$ and $t+4$.

Permanent layoffs lead to substantial temporary unemployment blemishes but far more enduring earnings scars. Displaced workers were out of work eight weeks more than their observably similar counterparts in the year of the separation, four additional weeks in period $t+1$, and two extra weeks at $t+2$. By year $t+3$ they were jobless only 1.5 weeks more than the peer group, and the $t+4$ increase was just six days (see Table 1, column a). Thus, at least 85 percent of the initial rise in joblessness dissipated prior to year $t+4$.⁷

In contrast, wage effects are large and lasting. The estimates in column a of Table 1 imply that base-year weekly earnings of job losers were 10.0 percent below those of their nondisplaced peers. This understates the reduction caused by dislocations, however, since period t wages partially reflect the (typically higher) pay received on the pre-separation job.⁸ It is therefore not surprising that the period $t+1$ wage differential was 1.6 times greater (16.1 percent) than the base-year effect. More significantly, almost none of the $t+1$ wage reduction dissipated with time. The earnings gap remained at 13.8 percent and 13.7 percent, respectively, in years $t+3$ and $t+4$, which was 85 percent of the disparity predicted for year $t+1$.⁹

The inclusion of controls for unobserved heterogeneity only slightly reduces the measured impact of base-year terminations. As expected, the estimated displacement effect

was somewhat larger when Y_{t-3} was added to the regressions (Table 1, column b) than when Y_{t-1} was included (column c). Even in the latter case, however, unemployment increased temporarily (by 7.1 weeks in year t and by 3.7 weeks in year $t+1$), and the wage loss remained above 10 percent in periods $t+2$ through $t+4$. If anything, addition of the lagged dependent variables strengthens the earlier finding of unemployment blemishes and permanent wage scars. This is seen by noting, that although the unemployment effect fell to around one week by period 4, the upper (lower) bound on the corresponding wage loss remained at 13.1 (10.6) percent.

The coefficient on D_{t+5} , in column d of Table 1, indicates that unobserved heterogeneity accounted for a 0.9-week disparity in annual unemployment and a 4-percent wage differential between displaced and nondisplaced workers. Subtracting this from the coefficients on D_t , the net increase in unemployment was 7.9 weeks at time 0, 3.8 weeks in period $t+1$, but less than 1 week annually in periods $t+3$ and $t+4$. Conversely, the estimated wage loss exceeded 11 percent in each of years $t+2$ through $t+4$, which was almost 90 percent as large as the maximum reduction observed in period $t+1$. Interestingly, these displacement effects are quite close to the lower-bound estimates presented in column c of Table 1 and again indicate transitory employment shocks but lasting earnings changes.

III. Summary

Although permanent loss of jobs leads to unemployment distinguished by its long duration, there is no evidence that these initial difficulties translate into lasting scars. Conversely, involuntary terminations typically result in a significant loss of long-term earnings potential. Four years after displacement, job losers are out of work only one week more than their nondisplaced counterparts but continue to earn 10–13 percent less. The lasting wage reductions suggest significant worker attachments to specific jobs. Future research is needed to investigate the sources of these attachments.

⁷Ellwood (1982) also finds that current unemployment has only a small effect on future joblessness. His results are for teenagers.

⁸For example, individuals displaced in July worked more than half the base year in the predisplacement position.

⁹Evidence of persistent wage losses has also recently been obtained by Robert Topel (1989). The wage-equation model in column a of Table 1 was also estimated using the standard two-stage correction for sample-selection bias. Except for period t , for which the estimates indicated that workers with low potential wages were more likely to be reemployed, the ordinary and two-stage least-squares estimates were virtually identical. The latter, if anything, showed greater persistence of wage losses.

APPENDIX

Data Set and Variable Construction

Data were taken from the 1969–1982 waves of the *Panel Study of Income Dynamics* (PSID). The PSID was obtained from the Inter-University Consortium for Political and Social Research (ICPSR); requests for descriptions of the data set and for the raw data should be directed to the ICPSR.

Analysis was restricted to household heads between the ages of 21 and 65 during the 1971–1975 base years who: 1) participated in the labor force during some part of the base year (t) and the following five years; 2) received earnings during at least one of the years $t-3$ or $t-2$; and 3) fulfilled the sampling criteria specified in footnote 3. Respondents were excluded if the head of household had changed during the relevant sample period or if they retired during the five years subsequent to the base year.

All data manipulations and analyses were performed using SAS (SAS Institute, 1985) on the Boston University mainframe computer, with the exception of the TOBIT regressions which were estimated using LIMDEP (William H. Green, 1986).

Individuals were defined to be displaced if they involuntarily terminated jobs in the base period [or in year 5 for the comparison group described in equation (3)] and failed to return to the old employer by the end of the second full calendar year following the separation. Dependent variables used in the analysis were weeks of calendar-year unemployment and the log of weekly wages. The latter were calculated by taking the natural logarithm of real annual earnings divided by number of weeks worked, with annual earnings adjusted to 1972 prices using the GNP deflator. Missing values were assigned for periods in which the natural log of weekly wage was less than 3 (this corresponds to weekly wages of less than \$20).

Except for the lagged dependent variables, the regressors are all dummy variables and refer to individual or job characteristics in the base year. They equal 1 if the following are true (and 0 otherwise).

Experience: Labor market experience is less than 10 years. Data on actual labor market experience is available and used beginning in 1974. For earlier years, experience is calculated as 1974 experience less the difference between 1974 and the survey date (e.g., in 1972, experience was set equal to 1974 experience less 2 years).

School: Education is less than or equal to 12 years.

Married: Respondent is married or permanently cohabiting.

Female: Respondent is female.

Nonwhite: Respondent is black or Spanish-American.

Age: Age is greater than 55 years old.

City1: City size is greater than 100,000.

City2: City size is less than 25,000.

Blue Collar: One-digit predisplacement occupation code is 5, 6, or 7.

Manufacturing: One-digit predisplacement industry code is 3 or 4.

Professional: One-digit predisplacement occupation code is 1 or 2.

Tenure1: Predisplacement seniority is 1–3 years.

Tenure2: Predisplacement seniority is 4–9 years.

Tenure3: Predisplacement seniority is 10–19 years.

Tenure4: Predisplacement seniority is at least 20 years.

Survey Year: Four dummy variables were included indicating the survey years 1972–1975 (1971 is the excluded category.)

Structural Determinants of Real Exchange Rates and National Price Levels: Some Empirical Evidence

By JEFFREY H. BERGSTRAND*

Contrary to the long-held notion of purchasing power parity (PPP), economists have found systematic evidence that the general level of prices across countries at a point in time varies dramatically. Irving B. Kravis, Alan W. Heston, and Robert Summers (1982), for example, report that some countries' national price levels are no more than *one-third* the U.S. price level. Extensions of this work show that such departures from PPP have persisted for decades.

Recently, efforts have been made to explain systematically these persistent, or structural, departures from PPP. Pioneering work by Kravis and Robert E. Lipsey (1983, 1987, 1988) has demonstrated that a positive correlation between the price level and (real) per capita gross domestic product is robust across numerous cross-sectional specifications. For instance, using data from Kravis et al. (1982 table 6-12), 87 percent of the variation in national price levels (PL) of 21 countries¹ in 1975 is explained by per capita GDP (y) and a constant:

$$(1) \quad \ln(PL) = 2.20 + 0.56 \ln y$$

(12.25) (11.72)

($\bar{R}^2 = 0.87$, RMSE = 0.18; t statistics in parentheses).

I am grateful to Ron Balvers, Tom Bundt, Jim Hartigan, Ron Jones, Norman Miller, J. David Richardson, Rich Sheehan, and two anonymous referees for helpful comments on an earlier draft, which was presented at the Western Economics Association annual meeting, June 1989, in Lake Tahoe, Nevada. Financial support from the Center for Research in Business at the University of Notre Dame, with funding from the Transamerica Fund, is gratefully acknowledged.

¹The 21 countries are India, Sri Lanka, Thailand, the Philippines, Korea, Columbia, Jamaica, Brazil, Yugoslavia, Ireland, Italy, Spain, the United Kingdom,

Although Christopher Clague (1986) showed that other "structural" characteristics (such as the trade balance, tourism receipts' share of GDP, and minerals' share of GDP) have significant explanatory power when also included, *why* per capita GDP has such a robust empirical correlation to the price level and *what* economic factor(s) it represents have not yet been determined. In the study of structural determinants of the price level, the two predominant competing theories for per capita GDP's role are the productivity-differentials (or Ricardian) model usually attributed to Bela Balassa (1964) and Paul A. Samuelson (1964) and the relative-factor-endowments (or Heckscher-Ohlin) model discussed in Jagdish N. Bhagwati (1984).

The purpose of this study is to distinguish empirically these two competing supply-oriented hypotheses, along with a possible third *demand*-oriented hypothesis that has received virtually no attention. This third hypothesis suggests that, assuming nonhomothetic tastes,² price levels are higher in countries with higher per capita GDP's because nontraded services are luxuries in consumption while traded commodities are necessities. The empirical evidence in the second section suggests that the null hypothesis that per capita income has no effect on the national price level via this demand channel is rejected.

Japan, Austria, the Netherlands, Belgium, France, Denmark, Germany, and the United States. These countries were selected for constraints that will become apparent in Section II.

²Nonhomothetic tastes imply that the income-expansion path through the indifference curves of the representative consumer is not a straight line through the origin, generating an income elasticity of demand greater (less) than 1 for the nontraded service (traded commodity).

I. Theoretical Issues

Across countries, price levels are expected to be positively associated with [real per capita] income because prices of nontradeables [mainly services] are higher relative to prices of tradeables [mainly commodities] in rich countries than in poor countries.

[Kravis and Lipsey, 1988 p. 474]³

Consider the national price level as decomposable into (nontraded) services' prices and (traded) commodities' prices. According to the productivity-differentials model, rich countries are believed to have absolute productivity advantages in both services and commodities, but a relative productivity advantage in commodities. Consequently, the relative price of services to commodities (henceforth, the "relative price level" or "real exchange rate") will be higher in countries with larger per capita incomes. Since commodity arbitrage will tend to equilibrate commodities' prices across countries, the national price level will tend to be higher in rich countries, since their price of services relative to commodities is higher. One would then expect to find a similar high correlation between the relative price level (p) and per capita GDP across countries. Indeed, using the same data set as for regression equation (1), 85 percent of the variation in relative prices is explained by per capita income and a constant:

$$(2) \ln p = 2.20 + 0.50 \ln y \\ (12.48) \quad (10.58)$$

($\bar{R}^2 = 0.85$, RMSE = 0.17; t statistics in parentheses).

The predominant alternative explanation to productivity differentials involves relative factor endowments. In the two-good, two-

factor, relative-factor-endowments model, services (commodities) are assumed to be relatively labor-intensive (capital-intensive) in production. Relatively capital-abundant rich countries will have a comparative advantage in producing commodities, so that the price of services relative to commodities, and thus the national price level, will be higher in countries with larger per capita income.

However, little attention has been devoted to a Linder-type hypothesis as an alternative demand-side explanation for why per capita GDP is positively correlated with the real exchange rate and national price level. Although Rudiger Dornbusch (1988) and J. Peter Neary (1988) noted that shifts in tastes as well as in technologies and relative factor endowments can change the real exchange rate, no one has attempted to link explicitly differences in tastes across countries with differences in their per capita GDP's (as suggested in Linder [1961]) and differences in their real exchange rates. To illustrate these linkages, consider the following model (see Neary [1988] for a more general discussion using trade-expenditure functions).

A. Demand

Staffan Burenstam Linder (1961 p. 94) suggested that a "whole array of factors influences the demand structure of a country," but that per capita income was likely to be the "most important single factor." He argued:

At higher [real per capita] incomes, products of different kinds, although filling the same basic needs, are likely to replace less sophisticated types of products; furthermore, products filling new needs are added. . . . But the more we divide total production into subgroups, the greater will be the variations in income elasticity. [pp. 94-5]

I formalize the Linder claim that per capita income has a dominant influence on the structure of demand by assuming the following nonhomothetic, nested Cobb-Douglas-Stone-Geary utility function for the

³Bracketed terms added. In the Kravis et al. (1982) data, the empirical distinction between nontradeables and services and between tradeables and commodities is fairly minor and rests entirely upon the treatment of construction. Tradeables consist of all commodities except construction; nontradeables consist of all services plus construction (see Kravis et al., 1982 p. 193). Consequently, reference here will be made to non-traded services and traded commodities.

representative consumer-worker:

$$(3) \quad u = (x_T - \bar{x}_T)^\delta (x_N - \bar{x}_N)^{1-\delta} \\ 0 < \delta < 1$$

where x_T (x_N) is the amount consumed of the traded commodity (nontraded service) and \bar{x}_T (\bar{x}_N) is an exogenous minimum-consumption requirement that exists for the traded commodity (nontraded service), common to the Stone-Geary utility function. Ready examples of traded commodities and nontraded services that would have minimum per capita consumption requirements are food and government-provided police and fire services, respectively. Assume the budget constraint

$$(4) \quad y = x_T + px_N$$

where y is real income of the representative consumer-worker and p is the relative price of the nontraded service, both expressed in terms of the traded commodity (the numeraire).

This utility structure yields nonunitary income elasticities of demand for the two products. Maximizing (3) subject to (4) yields first-order conditions solvable for demand functions:

$$(5) \quad x_N = (1 - \delta)p^{-1}(y - \bar{x}_T) + \delta\bar{x}_N$$

$$(6) \quad x_T = \delta y + (1 - \delta)\bar{x}_T - \delta p\bar{x}_N$$

The differing income elasticities of demand implied by this structure for the two products are made more transparent following some mathematical manipulation to yield

$$(7) \quad \hat{x}_N = - \left(1 - \frac{\delta\bar{x}_N}{x_N} \right) \hat{p} \\ + \left(1 + \frac{(1 - \delta)\bar{x}_T - \delta p\bar{x}_N}{px_N} \right) \hat{y}$$

$$(8) \quad \hat{x}_T = - \left(\frac{\delta p\bar{x}_N}{x_T} \right) \hat{p} \\ + \left(1 - \frac{(1 - \delta)\bar{x}_T - \delta p\bar{x}_N}{x_T} \right) \hat{y}$$

where \hat{x} denotes $dx/x = d(\ln x)$. In the cross-country context of this paper, \hat{x} is interpreted as a percentage difference between two countries. For example, a 1-percent-higher per capita income in country B relative to country A will cause B's per capita demand for the nontraded service to be $1 + [(1 - \delta)\bar{x}_T - \delta p\bar{x}_N]/px_N$ percent higher than A's and will cause B's per capita demand for the traded commodity to be $1 - [(1 - \delta)\bar{x}_T - \delta p\bar{x}_N]/x_T$ percent higher than A's. The nontraded service (traded commodity) will be the luxury (necessity) in consumption if the parameter-weighted minimum-consumption requirement for the traded commodity, $(1 - \delta)\bar{x}_T$, exceeds that for the nontraded service (expressed in the numeraire), $\delta p\bar{x}_N$, and vice versa.

The demand for the nontraded service relative to the traded commodity (X) is

$$(9) \quad \hat{X} = (\hat{X}_N/\hat{X}_T) = (\hat{x}_N/\hat{x}_T) = \hat{x}_N - \hat{x}_T \\ = -\sigma_D \hat{p} \\ + \left(\frac{x_T + px_N}{x_T px_N} [(1 - \delta)\bar{x}_T - \delta p\bar{x}_N] \right) \hat{y}$$

where X_N (X_T) denotes aggregate demand for the nontraded service (traded commodity) and σ_D is the elasticity of substitution in consumption; formally, $\sigma_D = 1 - (\delta\bar{x}_N/x_N) - (\delta p\bar{x}_N/x_T)$, which is likely to be positive and close to 1. Per capita GDP's coefficient may be positive or negative; a 1-percent-higher per capita income in country B will cause B's relative demand for the nontraded service to be higher (lower) than A's if the weighted minimum-consumption requirement for the traded commodity is greater (less) than that for the nontraded service.

Is there reason to believe a priori that the minimum-consumption requirement per capita for traded commodities exceeds that for nontraded services? The theoretical model reveals no such presumption. However, casual observation of per capita consumption patterns of the poorest countries in Kravis et al.'s (1982) data set (group I) suggests that the minimum-consumption re-

quirement for commodities is likely to dwarf that for services. The only product group in Kravis et al. (1982) that included commodities (services) *exclusively* was food (government compensation for services provided). In terms of international prices, group I's per capita GDP in 1975 was only 9 percent of U.S. per capita GDP; yet 38 percent of this group's low per capita GDP was spent on food, while only 5 percent was spent on government compensation for services provided. Also, Linda C. Hunter and James R. Markusen (1988) used the same data set to estimate linear expenditure systems by Kravis et al.'s (1982) product groups; the results suggested that nontraded services (traded commodities) had income elasticities greater (less) than 1. Nevertheless, the empirical results in Section II will systematically reveal whether the coefficient on \hat{y} is positive or negative.

Finally, for the special case in which \bar{x}_N is zero, the coefficient on \hat{y} is positive, and σ_D equals 1. This will be of interest for Section II.

B. Supply

The purpose of this section is to motivate a function for the supply of nontraded services relative to traded commodities in the representative country. I assume a standard simple-general-equilibrium framework similar to that in Ronald W. Jones (1965) for production of these two goods, using two factors: capital (K) and consumer-workers (L), the endowment of which is fixed at a point in time for each country. Perfectly competitive firms are assumed to minimize costs given the constant-returns-to-scale technology, yielding the optimum input requirements per unit of output:

$$(10) \quad \beta = \begin{bmatrix} \beta_{LN} & \beta_{LT} \\ \beta_{KN} & \beta_{KT} \end{bmatrix}.$$

Each β_{ij} ($i = L, K$; $j = N, T$) is a function of the relative factor price (i.e., the wage rate [W] relative to the rental rate on capital [R]) and the state of productivity (τ_{ij}) in the country. An assumption of full employment

of both factors requires

$$(11) \quad \beta_{LN}X_N + \beta_{LT}X_T = L$$

$$(12) \quad \beta_{KN}X_N + \beta_{KT}X_T = K$$

where L (K) is the overall endowment of labor (capital) and X_N (X_T) is aggregate production of the nontraded service (traded commodity). In a competitive equilibrium with both goods produced, unit costs must reflect market prices of the goods:

$$(13) \quad \beta_{LN}W + \beta_{KN}R = P_N$$

$$(14) \quad \beta_{LT}W + \beta_{KT}R = P_T$$

where all factor prices (W, R) and goods prices (P_N, P_T) are expressed in terms of a monetary unit, as in Jones (1965).

The production framework follows closely sections 2, 3, and 9 in Jones (1965). Hence, derivations for the solution need not be reproduced but are available from the author upon request. With some mathematical manipulation, the production framework can be solved for the supply of nontraded services relative to traded commodities (X) as a function of their relative price level (p), the capital:labor endowment ratio ($k = K/L$), and the level of productivity in traded commodities relative to nontraded services (Π):

$$(15) \quad \hat{X} = \sigma_S \hat{p} - (1/|\lambda|) \hat{k} - (1 + \sigma_S) \hat{\Pi}$$

where the level of productivity in each industry is a weighted average of the level of productivity of each factor in that industry (τ_{ij}), $|\lambda| = \beta_{LN}X_N/L - \beta_{KN}X_N/K = \beta_{KT}X_T/K - \beta_{LT}X_T/L$, σ_S is the elasticity of substitution between goods in production (along the transformation schedule) as in Jones (1965), and $\sigma_S > 0$. In the cross-country context of this paper, a 1-percent-higher level of productivity in traded commodities relative to nontraded services in B compared with A will cause B's relative supply of nontraded services to traded commodities to be $1 + \sigma_S$ percent lower than A's. The coefficient for the capital:labor ratio is ambiguously signed, depending upon rela-

tive factor intensities in production. If nontraded services are relatively labor-intensive in production (i.e., $|\lambda| > 0$), a 1-percent-higher capital:labor ratio in B relative to A will cause B's supply of nontraded services relative to traded commodities to be lower than A's.

C. Equilibrium

Demand function (9) and supply function (15) can be solved for the equilibrium relative price level (or real exchange rate), p , and the equilibrium relative output level, X , in the representative country:

$$(16) \quad \hat{p} = \frac{1 + \sigma_s}{\sigma_D + \sigma_s} \hat{\Pi} + \frac{1}{(\sigma_D + \sigma_s)|\lambda|} \hat{k} + \frac{[(1 - \delta)\bar{x}_T - \delta p\bar{x}_N](x_T + px_N)}{(\sigma_D + \sigma_s)(x_T px_N)} \hat{y}$$

$$(17) \quad \hat{X} = -\frac{\sigma_D(1 + \sigma_s)}{\sigma_D + \sigma_s} \hat{\Pi} - \frac{\sigma_D}{(\sigma_D + \sigma_s)|\lambda|} \hat{k} + \frac{\sigma_s[(1 - \delta)\bar{x}_T - \delta p\bar{x}_N](x_T + px_N)}{(\sigma_D + \sigma_s)(x_T px_N)} \hat{y}.$$

Equation (16) demonstrates how the productivity-differentials, relative-factor-endowments, and Linder hypotheses are all potentially relevant for explaining variation across countries in the equilibrium relative price of nontraded services to traded commodities (and the general price level). A 1-percent-higher productivity in traded commodities relative to that in nontraded services in country B compared with country A will cause B's relative price level to be $(1 + \sigma_s)/(\sigma_D + \sigma_s)$ percent higher than A's, supporting the productivity-differentials model. A 1-percent-higher capital:labor ratio in B relative to A will cause B's relative price level to be $1/[(\sigma_D + \sigma_s)|\lambda|]$ -percent higher than A's if nontraded services are relatively labor-intensive in production ($|\lambda| > 0$), supporting the relative-factor-endowments hypothesis. A 1-percent-higher per capita income in B relative to A will cause B's relative price level to be higher if the weighted minimum-consumption require-

ment for traded commodities exceeds that for nontraded services, implying an income elasticity of demand for nontradeables (tradeables) greater (less) than one.

Thus, all three hypotheses potentially can explain structural variation in the real exchange rate. Since per capita income is correlated positively with the capital:labor ratio and the level of productivity in commodities relative to services across countries, earlier studies have not tried to distinguish empirically among the relative importances of these three channels. However, if capital:labor ratios and relative-productivity measures are available, a ready method of distinguishing between the demand and supply roles of per capita income is to examine empirically the cross-country relationship between per capita income and the output of nontraded services relative to traded commodities, as demonstrated by equation (17). A 1-percent-higher productivity in traded commodities relative to nontraded services in B compared with A will cause B's output of nontraded services relative to traded commodities to be $\sigma_D(1 + \sigma_s)/(\sigma_D + \sigma_s)$ percent lower than A's. A 1-percent-higher capital:labor ratio in B relative to A will cause B's output of nontraded services relative to traded commodities to be $\sigma_D/[(\sigma_D + \sigma_s)|\lambda|]$ percent lower than A's. However, a 1-percent-higher per capita income in B relative to A will cause B's relative output of nontraded services to traded commodities to be higher than A's if, to be consistent with equation (16), the income elasticity of demand for nontradeables (tradeables) is greater (less) than one.

The theoretical arguments are illustrated in Figure 1. Country B might have a higher relative price level than A because B has a higher productivity in traded commodities relative to nontraded services or a higher capital:labor ratio (assuming nontraded services are labor intensive) or both, causing a lower supply of nontraded services relative to traded commodities. However, if nontraded services (traded commodities) are luxuries (necessities) in consumption, higher-per-capita-income country B might have a higher relative price level than A

FIGURE 1. RELATIVE DEMAND AND RELATIVE SUPPLY CURVES FOR COUNTRIES A AND B

because of a higher *relative demand* for nontraded services. Only by examining empirically both reduced forms or their underlying structural equations could one hope to disentangle these three influences; these are examined next.

II. Empirical Results

Recent estimates of capital and labor endowments and of levels of productivity in commodities and in services across countries now make it possible to distinguish empirically among the three competing explanations for the robust positive correlation between countries' price levels and their per capita GDP's. Edward E. Leamer (1984) provides measures of capital and labor endowments for numerous countries circa 1975, of which 23 countries overlap with the 34 in Kravis et al. (1982) and Kravis and Lipsey (1983). The technique of Kravis et al. (1983) could be used to approximate the level of productivity in commodities relative to services for 21 of these countries.⁴

⁴This explains the 21 countries for regressions (1) and (2). Capital and labor (LABOR1) for 1975 are from Leamer (1984 appendix table B.1). The level of productivity in (traded) commodities relative to (non-traded) services, $\Pi = \Pi_T / \Pi_N$, is approximated by the

A. Reduced-Form Estimates

Given these 1975 estimates of capital: labor endowment ratios (k) and levels of productivity in commodities relative to services (Π), econometric analogues to reduced-form equations (16) and (17) could be estimated using ordinary least squares (OLS). Estimation of the log-linear version of (16) yields:⁵

$$(18) \quad \ln p = -2.81 + 0.17 \ln \Pi + 0.23 \ln k + 0.18 \ln y$$

(12.68) (2.25) (2.84) (1.67)

($\bar{R}^2 = 0.90$, RMSE = 0.14; t statistics in parentheses). Equation (18) suggests that each supply-oriented hypothesis for the relationship between the real exchange rate and per capita GDP has partial explanatory power. The level of productivity in commodities relative to services has the expected positive effect on the price of services relative to commodities, according to the productivity-differentials hypothesis; the coefficient estimate is statistically significant at the 2.5-percent level (one-tailed t test).⁶

ratio of national output in commodities industries to the level of employment in commodities industries divided by the ratio of national output in services industries to the level of employment in services industries, that is, $(X_T / L_T) / (X_N / L_N)$, the inverse of the calculation in Kravis et al. (1983) for the level of productivity in services relative to commodities. Employment data are from the International Labour Organization's (1979) *Year Book of Labour Statistics*, as in Kravis et al. (1983). The output of commodities relative to services and all other data are from table 6-12 in Kravis et al. (1982).

⁵Treating the coefficients of $\hat{\Pi}$, \hat{k} , and \hat{y} in (16) and (17) as constants, indefinite integration of those equations yields log-linear forms with constants appended.

⁶One referee noted that differences across countries in $(X_T / L_T) / (X_N / L_N)$, the proxy for Π_T / Π_N , could largely reflect differences across countries in their capital per unit of labor in (traded) commodities relative to (nontraded) services—the latter denoted k_T / k_N —rather than differences in Π_T / Π_N . As noted in Section I, each country's β_{LT} ($= L_T / X_T$) and β_{LN} ($= L_N / X_N$) are negative functions of the country's states of productivity (τ_{LT} and τ_{LN} , respectively) and of the country's relative factor price (W / R). Assuming

The capital:labor endowment ratio has a positive effect on the relative price level, suggesting that services are relatively labor-intensive in production, consistent with the relative-factor-endowments hypothesis; the coefficient estimate is significant at the 1-percent level. The presence of both k and Π has significantly eroded the explanatory power of per capita income.⁷

However, real per capita income is still positively related to the price of services relative to commodities, albeit only at the 10-percent significance level. In the context of the model, the remaining statistical significance of this coefficient suggests that per capita income may also be influencing the relative price level through demand. How-

ever, this positive estimate is also consistent with per capita GDP having some residual influence through supply on the real exchange rate unrelated to capital:labor ratios and relative productivity levels. A ready method of distinguishing empirically between a potential demand or supply role for per capita income is to examine the cross-country relationships between the output of services relative to commodities and Π , k , and y , as suggested by equation (17).

Ordinary-least-squares estimation of the log-linear version of (17) yields

$$(19) \quad \ln X = 0.45 - 0.10 \ln \Pi - 0.26 \ln k \\ (1.42) \quad (0.89) \quad (2.17) \\ + 0.26 \ln y \\ (1.73)$$

Hicks neutrality, $\hat{\tau}_{LN} - \hat{\tau}_{LT} = \hat{\Pi}_T - \hat{\Pi}_N = \hat{\Pi}$, implying that $(X_T/L_T)/(X_N/L_N)$ is a positive function of $\hat{\Pi}$; yet $(X_T/L_T)/(X_N/L_N)$ could also be reflecting (k_T/k_N) if countries are using different cost-minimizing relative factor intensities owing to differing wage:rental ratios [variation in which is not already explained by capital:labor endowment ratios, another right-hand-side variable in eq. (18)]. However, this latter possibility does not seem to be empirically confirmed. While calculations of k_T/k_N for all 21 countries was beyond the scope of this study, ready estimates of such intensities were available for six "country groups" (I-VI), reported in Kravis et al. (1983 table 12). Those authors found no systematic pattern for k_T/k_N across country groups. Moreover, I found no systematic correlations of k_T/k_N with respective observations on $(X_T/L_T)/(X_N/L_N)$, y , k , p , or X for these groups.

Note that this specification differs from that in Clague (1986), which retained per capita GDP as a proxy for (non-natural-resource) relative factor abundances and relative productivity levels. Clague notes, "Ideally, we would like to treat real [per capita] income as an endogenous variable, but since we cannot measure resource endowments per capita, efficiency levels, and other determinants of real income, we are forced to use [per capita income] as an exogenous variable" (p. 320). Not surprisingly, a regression of per capita GDP on k and Π reveals strong evidence for interpreting per capita GDP as a proxy for capital:labor ratios and for levels of productivity in commodities relative to services, respectively. The estimated regression for the same 21 countries is

$$\ln y = -0.31 + 0.68 \ln k + 0.31 \ln \Pi \\ (0.63) \quad (7.88) \quad (2.05)$$

($\bar{R}^2 = 0.85$, RMSE = 0.31; t statistics in parentheses).

($\bar{R}^2 = 0.13$, RMSE = 0.20; t statistics in parentheses). Consistent with the relative-factor-endowments and productivity-differentials models as well as equation (18), a higher level of productivity in commodities relative to services or a higher capital:labor ratio is associated with a lower output of services relative to commodities, although the coefficient estimate for Π is not statistically significant. Moreover, a higher per capita income is associated with a higher relative output of services to commodities. In the context of the model, this result suggests that a higher per capita income causes a higher relative price level because of a greater demand for nontraded services relative to traded commodities. The coefficient estimate for y is statistically significant at the 10-percent level (one-tailed t test).

B. Simultaneous-Equations Estimates

Although the results presented in reduced-form equations (18) and (19) are encouraging to the hypothesis that the positive relationship between per capita income and the relative price level is also attributable to a Linder-type demand channel, the statistical evidence is far from conclusive. Moreover, the coefficients from the reduced-form equations are nonlinear combinations of the structural parameters from the underlying

structural equations. Since this particular model is overidentified, the underlying structural parameter estimates for the relative demand and supply variables cannot be determined immediately from reduced-form equations (18) and (19).⁸

However, two-stage least squares (2SLS) conveniently enables determination of the structural parameter estimates of theoretical equations (9) and (15).⁹ Two-stage least-squares estimation of log-linear versions of (9) and (15) yields the following demand (D) and supply (S) equations for the relative output of services to commodities:

$$(20) \quad \ln X^D = -1.96 - 0.90 \ln p$$

(1.87) (2.10)

$$+ 0.40 \ln y$$

(1.79)

$$(21) \quad \ln X^S = 4.61 + 1.48 \ln p$$

(1.15) (1.07)

$$- 0.35 \ln \Pi - 0.60 \ln k$$

(1.00) (1.20)

(RMSE = 0.11 and 0.33, respectively; *t* statistics in parentheses).

Several points are worth noting. First, empirical implementation of theoretical structural equations (9) and (15) yields results consistent with the Linder-type demand hypothesis. The demand for services relative to commodities is significantly (at the 5-percent level, one-tailed *t* test) related to per capita income, holding constant the influences of relative factor endowments and productivity differentials on relative supply. In the context of the model, this suggests that the income elasticity of demand for nontraded services (traded commodities) is greater (less) than one.

⁸This system would be just identified if one of the supply variables were deleted.

⁹The *t* statistics reported are asymptotically valid. Given that there are only three exogenous variables, 2SLS estimation can only be used appropriately here to determine *relative* outputs and prices.

Second, the estimate of the elasticity of substitution in demand (σ_D), 0.9, is statistically significant and has a plausible magnitude. As noted in Section I, for the special case in which the minimum consumption requirement for nontraded services (\bar{x}_N) is zero, σ_D should equal 1 or $-\sigma_D = -1$. In fact, the linear restriction that the coefficient estimate equals -1 could not be rejected even at the 10-percent significance level ($F_{[1, 18]} = 0.056$). This suggests that \bar{x}_N is not significantly different from zero, consistent with earlier observations noted in Section I.

Third, the relative price level, the level of productivity in services relative to commodities, and the capital:labor endowment ratio all have the expected relationships with the supply of services relative to commodities, although their coefficient estimates are not significant. The linear restriction on this supply equation's coefficient estimates implied by theoretical supply function (15)—that the coefficients of the price and Π variables should sum to -1 —was tested also. This linear restriction was rejected at the 10-percent significance level, but could not be rejected at the 5-percent level ($F_{[1, 17]} = 3.838$).

Fourth, as noted in footnote 2, the empirical distinction between services and non-tradeables and between commodities and tradeables is a fairly minor one, resting on the treatment of construction activity. Equations (18)–(21) were also estimated using nontradeables/tradeables data instead of services/commodities data. The results are similar but are omitted here for brevity; these are available from the author upon request.

In concluding this section, I emphasize a key empirical result that has been omitted in this literature: the null hypothesis that per capita income has no effect on real exchange rates and national price levels *via demand* is rejected.

III. Conclusions and Policy Implications

This study has provided empirical evidence that the systematic cross-country relationship between real per capita incomes

and national price levels (or real exchange rates), commonly attributed to the supply-oriented productivity-differentials and relative-factor-endowments hypotheses, can also be attributed partly to a demand-oriented "Linder-type" hypothesis. Assuming nonhomothetic tastes, countries with higher real per capita income will exhibit, in equilibrium, stronger demand for nontraded services relative to traded commodities, raising their relative price. Empirical evidence showed that, even when differences across countries in capital:labor endowment ratios and levels of productivity in commodities relative to services are accounted for, real per capita income still has a significant positive correlation with relative price levels and outputs. The results are consistent with recent studies emphasizing the importance of nonhomotheticity of tastes for explaining consumption and trade patterns across countries (cf. Jerry G. Thursby and Marie C. Thursby, 1987; Hunter and Markusen, 1988). Yet with only 21 usable observations from the Kravis et al. (1982) data set, the results are only encouraging, not conclusive, and more empirical research along these lines seems warranted.

Finally, two policy implications are raised by the issues addressed in this study. First, some of the U.S. dollar's dramatic real appreciation vis-à-vis foreign currencies between 1980 and 1985 and the subsequent large real depreciation from 1985 to 1988 should not be attributed to "disequilibrium," or exchange-rate misalignment. Per capita GDP of most other major industrialized countries fell relative to that of the United States in the first half of the 1980's and rose subsequently, although not nearly by the magnitude of actual real exchange-rate changes. Second, the Plaza Accord of September 1985, which indicated that the major industrialized countries' governments coordinated an effort to facilitate the U.S. dollar's real depreciation toward some "zone," and massive 1988 coordinated central bank interventions, which revealed that the same countries coordinated an effort to prevent the dollar's depreciation below this zone, both suggest that the governments have some notion of the "equilibrium" real

exchange rate. The results here suggest that relative productivity levels, capital:labor ratios and tastes can explain as much as 90 percent of the variation across countries in real exchange rates. Consequently, the variation in such diverse real economic variables over time will tend to obscure the policy identification of the equilibrium real exchange rate.

The Winner's Curse: Experiments with Buyers and with Sellers

By BARRY LIND AND CHARLES R. PLOTT*

This paper presents a replication and extension of experiments with the "winner's curse" which were initiated in John Kagel and Dan Levin (1984, 1986) and Douglas Dyer et al. (1989). The common-value auction involves firms bidding for an item of unknown common value. Since the value of the item is unknown, the winners can bid more than the value and thereby lose money. The winner's curse occurs if the winners of auctions systematically bid above the actual value of the objects and thereby systematically incur losses. The phenomenon is said to occur possibly in the bidding for such natural resources as mineral rights, where the value of the mineral is unknown but each firm has an estimate of the value. Due to the field nature of the data, doubts have existed as to the actual existence of the curse. The Kagel and Levin (1986) paper tested for the existence of the phenomenon in a laboratory setting. The hope is that, by achieving a thorough understanding of the phenomenon as it might exist in simple laboratory environments, economists will become better equipped to identify and study the phenomenon in more-complex field settings.

Kagel and Levin (1986) report the existence of a winner's curse, but as is the case with any seminal experiment, it is impossible to control for everything. After seeing their data and studying their experimental

procedures, one finds that there exist alternative explanations for what they saw. The winner's curse involves buyers who pay more than the value of an item and therefore experience a loss. Monetary losses in an experiment pose a problem because the experimenter generally has no means of collecting money from subjects. Subjects, knowing this, have reason to believe that the downside risk on their actions is truncated, and thus they might be prone to more risky actions than would be the case if they were forced to suffer full losses. In order to minimize this effect, subjects are frequently given a cash stake which they can lose. Kagel and Levin (1986) were aware of the problem, and they provided such a stake and used experienced subjects. They also required subjects to leave the experiment if and when the stake was lost. While these procedures provide some control, the possibility that losses could have contributed to the existence of the winner's curse has not been completely eliminated (Robert Hansen and John Lott, 1991). After a loss or two, a subject's reserve could be sufficiently low that prospective losses could exceed the balance. Thus, inflated bids carry no additional risk. Furthermore, one could theorize that experience with the curse facilitates learning and caution even in people who have had experience with bidding on other occasions. According to that theory, the process of removing bankrupt subjects succeeded in removing subjects less prone to the curse (i.e., those who had the experience of losing money and might adjust their behavior accordingly). Thus, subjects more prone to the curse would remain in the experiment and contribute to the existence of the curse. The situation is complicated even further by the possibility that subjects' beliefs about the reaction of other subjects to potential bankruptcy could cause general departures

*Barry Lind is a senior undergraduate and Charles Plott is a professor of economics at the California Institute of Technology. The financial support of the National Science Foundation and the Caltech Experimental Economics and Political Science Laboratory is gratefully acknowledged. We also thank Robert Hansen, John Kagel, Dan Levin, and John Lott for their comments.

from symmetric Nash-equilibrium behavior. Thus, a skeptic could claim that the existence, magnitude, and persistence of the winner's curse in the Kagel and Levin (1986) data were direct consequences of the way that Kagel and Levin's experimental procedures dealt with substantial losses by subjects. The technique used by Dyer et al. is the same as that used in Kagel and Levin (1986), so similar questions might be raised about it as well.

The strategy of the research reported here is to look for the phenomenon using procedures that avoid the bankruptcy problems. Two different sets of procedures are used. First, the "winner's curse" experiment in which subjects might lose money was conducted simultaneously with a second experiment in which subjects were making money. The second set of procedures involved competitors as sellers in a common-value auction. The winner's curse can appear in this setting as the sale of an item for less than it is actually worth to the seller. The seller's loss occurs as an opportunity cost only, so the possibility of bankruptcy does not exist.

The experiments using these different sets of experimental procedures produced several results which are the substance of the paper.

1. The winner's curse was observed in both experimental settings. In essence, the Kagel and Levin results were replicated.
2. The winner's curse observed by Kagel and Levin (1984, 1986) was not a consequence of their experimental procedures.
3. The winner's curse might diminish in size or frequency but does not completely dissipate over time.
4. The winner's curse is a general phenomenon exhibited by most agents.
5. Theories of "suboptimal" behavior advanced as explanations of the phenomenon do not explain the data as well as does the completely rational model in which the phenomenon does not exist at all theoretically.

The paper is organized as follows. In Section I, the experimental design is outlined. In Section II, some competing models are

discussed. Section III contains a statement of the measurement system. The results are in Section IV. The concluding section contains a discussion of conjectures that might advance an understanding of the phenomenon.

I. Experimental Design

The experiments were two types of common-value auctions. The first type of experiment was the common-value auction as conducted by Kagel and Levin (1984, 1986) in which buyers bid for an item of unknown value. Subjects agreed that if they suffered losses they would work them off at \$10 per hour.¹ In experiment 1, subjects participated in a sealed-bid private-value auction at the same time that they participated in a common-value auction in which the winner's curse might occur. In the second experiment, subjects participated in both a common-value auction in which they were buyers (experiment 2) and also in a common-value auction in which they were sellers (experiment 3). (In other words, experiments 2 and 3 were run simultaneously on the same subjects.) These secondary auctions constituted a source of funds which reduced the likelihood of bankruptcies in case the winner's curse was operative. These procedural changes were implemented so that subjects had full financial liability in the range of financial exposures that were likely to exist in the experiments.

The second type of experiments (experiments 3-5) were common-value auctions with competition among sellers as opposed to buyers. The sellers tendered offers to sell an item of unknown value. Each seller was given one item to sell. Their option was to keep the item and collect its value or sell the item and collect the revenues from the sale. The person with the lowest offer sold his item and received the asking price, while everyone else kept the item and received the value. In this common-value selling auc-

¹Only one subject suffered sufficient loss to be required to work. He worked about one hour to cover an \$8 loss.

tion, all subjects earned positive profits, including the winner, but the winner could suffer opportunity costs by selling the item for less than the amount received by those who did not sell the actual value of the item.

The experiments were conducted at the California Institute of Technology, using undergraduates as subjects. Most of the subjects had participated in other experiments prior to these and were familiar with the experimental environment. The subject pool serves as a partial control for the hypothesis that the curse might be due to confusion about instructions. The instructions read to the subjects are given in the Appendix. Prior to the experiment, the common values of the objects were determined by realization from a random-number table. Given the value of the object, "clues" or "signals" were drawn for each subject independently. Each subject was given a stack of slips of paper which contained the clues to the common value of the items being auctioned. The slips were stapled so that only the clue for the current period could be observed. The subject observed the clue and then submitted a bid. After the auction, all bids, signals, and the common value were posted. The winner was then announced. The subject removed the top slip to expose the clue for the next period.

The clue was called a signal about the true value of the item to be auctioned. The value of the item was randomly chosen from the range (x, \bar{x}) . If v was the item's value, then the signals were randomly chosen over an interval $(v - \varepsilon, v + \varepsilon)$, where ε is a positive value set by the experimenter. In order to avoid the winner's curse, the bidder must recognize that, if he wins and thus buys (sells) the object, then he probably has the highest (lowest) signal, which is probably above (below) the item's value. Therefore, in order for the person not to lose money, (forgo profits) he must bid (ask) significantly less (more) than this signal.

Five experiments were conducted. The first two were buyer markets which replicated one of the experimental settings of Kagel and Levin (1984, 1986). The next three were seller markets. All experiments were

conducted with seven subjects. Experiments 1 and 2 had the same set of predrawn signals, and experiments 4 and 5 had the same set of predrawn signals. The value of ε for the buying auctions was \$30, and it was 200 francs in the selling auctions. The range from which v was drawn was $(x, \bar{x}) = (\$25, \$225)$ for the buyer auctions and $(x, \bar{x}) = (150 \text{ francs}, 1,500 \text{ francs})$ for the seller auctions. (The franc values were \$0.0025, \$0.001, and \$0.0007 for experiments 3, 4, and 5, respectively.) The parameter choices reflect an attempt to identify unambiguously the curse, should it exist. The models reviewed below suggest that the curse becomes more severe with larger ε and a larger number of people. The parameters are those of Kagel and Levin (1986) that make the curse severe. Another consideration was cost. In the seller auctions, all subjects (except the seller) were paid the value of the item, which makes the experiments potentially expensive. For example, if the value in the seller auction had been drawn from the same distribution over dollars that it was drawn from in the buyer auction, then the cost of the experiment would have been on the order of \$875 ([expected value of v] $\times 7$) per period. The scaling factor that was chosen to reduce the cost keeps ε equal to the same proportion of the range of v and also permits many periods. This creates an obvious difference in marginal dollar stakes between the two types of experiments, with the potential "losses" due to departures from Nash behavior being very small in the selling experiment. Should otherwise inexplicable differences in behavior be observed, the magnitude of incentive would be an obvious line of research to pursue.

II. Models

Assume that v is drawn from a uniform distribution. Assume that each x_i is drawn independently from a uniform distribution over the interval $[v - \varepsilon, v + \varepsilon]$. If x_i is the signal observed by individual i and the structure is common knowledge, the theoretical problem is to model how i chooses a bid as a function of x_i .

At least four models make sense. The first is the *risk-neutral Nash-equilibrium model* of the associated bidding game.² The second model is based on the hypothesis that individuals make a specific type of calculation error but still conform to the general principles of game theory. We call this the *strategic-discounting model*. The third model is based on the hypothesis that people do not behave strategically. They only bid the expected value as if the situation were a simple second-price auction of a lottery and not one in which strategies might be important. This model is called the *naive model*. The fourth model, called the *private-value model*, postulates that individuals bid as if x_i were a private value of the object for each i . That is, individuals fail to understand the basic statistical relationship between value and signals.

The optimal bidding strategy according to the risk-neutral Nash-equilibrium model (RNNE) is to bid as a function of the signal (x_i). Under the buying auction, the optimal strategy is

$$(1) \quad b(x_i) = x_i - \varepsilon + Y$$

$$Y = [2\varepsilon / (n+1)]$$

$$\exp[-(n/2\varepsilon)(x_i - (\bar{x} + \varepsilon))]$$

where n is the number of subjects. Under the selling auction, the RNNE optimal strategy is

$$(2) \quad b(x_i) = x_i + \varepsilon - Y$$

$$Y = [2\varepsilon / (n+1)]$$

$$\exp[-(n/2\varepsilon)(-x_i + (\bar{x} - \varepsilon))].$$

A strategic-discounting model (SD) is postulated by Kagel and Levin (1986) for buyer auctions. The model is based on the hypothesis that individuals fail to recognize that the auction winner will be the subject with the highest signal. Kagel and Levin's strategic-discounting model can be general-

ized to the seller auction. The equations for the optimal bidding strategy under the assumption that the bidder fails to recognize that the winner has the highest (lowest) signal are

(3) buying auction:

$$b(x_i) = x_i - (2\varepsilon/n) + (Y/n)$$

(4) selling auction:

$$b(x_i) = x_i + (2\varepsilon/n) - (Y/n).$$

The above equations for the RNNE and SD models are only valid on the interval $\bar{x} + \varepsilon \leq x_i \leq \bar{x} - \varepsilon$.

The naive model (N) for both the buying auction and the selling auction simply has the bid equal to the signal. The bidding strategy for both types of auctions is

$$(5) \quad b(x_i) = x_i.$$

The final model, the private-value model (PV), holds that individual i makes the mistake of placing a private value x_i on the object and that the private value of each of the j others is independently drawn from the interval $x_i \pm \varepsilon$. By applying risk-neutral Nash theory to this situation, bidding functions can be derived. For buyers, the bidding function is

$$(6) \quad b(x_i) = x_i - \frac{\varepsilon}{n}$$

and for sellers it is

$$(7) \quad b(x_i) = x_i + \frac{\varepsilon}{n}.$$

III. Measurement Methodology

The four theoretical models lend themselves naturally to a single measurement system. The single regression for each individual,

$$(8) \quad b_{it} = \alpha_i + \beta x_{it} + \gamma Y_{it} + e_{it} \sim N(0, \sigma_i^2)$$

can be used as a measure of the accuracy of all four theoretical models. The equation

²Obviously, risk aversion is a natural extension. We have been unable to find a closed-form solution for the bidding functions.

TABLE 1—PARAMETER RESTRICTIONS IMPOSED BY COMPETING THEORETICAL MODELS

Model	Buying			Selling		
	α	β	γ	α	β	γ
Risk-neutral Nash equilibrium	-30	1	1	200	1	-1
Strategic discounting	-8.6	1	0.14	57.1	1	-0.14
Naive	0	1	0	0	1	0
Private value	-433	1	0	28.6	1	0

can be used for both buying auctions and selling auctions. A summary of the restrictions on the regression equation imposed by the competing theories is included as Table 1. As can be seen, all theoretical models predict $\beta = 1$. The intercept term can be interpreted as $\delta\epsilon$, where ϵ is the value of the range of the signal $\{x_i \in [v - \epsilon, v + \epsilon]\}$, so $\alpha = \pm 1\epsilon$ in the RNNE model, $\alpha = (2/n)\epsilon$ in the SD model, $\alpha = 0$ in the N model, and $\alpha = \pm(1/n)\epsilon$ in the PV model. For the RNNE model, γ is ± 1 ; it is $\pm 1/n$ for the SD model, and it is 0 for both the N and the PV models.

The measurement strategy is first to apply the unrestricted regression model. The coefficients can be compared to the theoretical values of the competing models. Then models with parameters as restricted by theory will be applied. The SSE of the unrestricted model can be used with the SSE of the restricted model to compute an F statistic (Chow test) for the hypothesis that the restrictions are not significantly different from the unrestricted measurements. The F statistic will also be used as a measure of the relative closeness of the competing models.

IV. Results

The results of primary interest bear on the existence of the winner's curse. Of secondary interest are results that might uncover the principles that govern individual decision behavior. The findings are summarized by five conclusions.

Conclusion 1: The winner's curse exists.

Evidence. The per-period profit from all auctions is used as a measure. In buying auctions, the profit is the actual value of the

object minus the purchase price of the auction winner. In selling auctions, the profit is the sale price of the object minus the actual price received by the winner. Thus, in selling auctions, a negative profit is an opportunity cost incurred because the item was sold for less than it was worth to the seller.

Table 2 lists the average per-period profits from all experiments. As can be seen, the winner suffers a loss in four of the five experiments on average. The table also reports the ratio of the number of auctions in which a loss occurred to the total number of auctions. In all cases, a large proportion of the auctions resulted in a loss. The only possible exception to the general tendency is experiment 4, which was characterized by a large number of attempts at collusion. In total, more than half of all auctions resulted in a loss.

Conclusion 2: The winner's curse persists with experience, but the magnitude and frequency of losses decline with experience.

Evidence. The frequencies of losses of the auction winners are divided into ten-period quartiles for every experiment in Table 3. The size of the average loss is also included in the table. As can be seen, the proportion of auctions in which losses occur is significantly greater than zero in all quartiles. Even after 20 or 30 auctions, the winners lose money more than 25 percent of the time. The frequency of losses decreases after the first 10 trials in all experiments except experiment 5.

The complete time-series of profits for experiment 5 is included as Figure 1. The figure also shows the profit that would have occurred if the agent had used the RNNE strategy. As can be seen, the winners' losses continue to occur even after 30 auctions.

TABLE 2—WINNER'S AVERAGE PROFIT AND THE LOSS FREQUENCIES
FOR ALL EXPERIMENTS
(PROFITS GIVEN IN DOLLARS, WITH FRANCS IN PARENTHESES)

Experiment	Average profit per period	Average RNNE predicted profit per period ^a	Number of periods with winner's loss (total number of periods)
1 (buyer)	-1.67 (-1.67)	11.13 (11.13)	12/20
2 (buyer)	-3.60 (-3.60)	8.85 (8.85)	10/17
3 (seller)	-0.022 (-8.88)	0.196 (78.44)	8/17
4 (seller)	0.021 (20.91)	0.069 (69.28)	13/35
5 (seller)	-0.013 (-18.55)	0.050 (70.85)	25/40

^aThe given RNNE equation is valid only for: $\bar{x} + \varepsilon \leq x_i \leq \bar{x} - \varepsilon$. Some of the winners' signals were not in this range, so no predicted RNNE profit is possible. Therefore, this average includes only periods for which the RNNE predicted profit can be calculated.

TABLE 3—FREQUENCY OF LOSSES FOR WINNERS IN ALL EXPERIMENTS
(PROFITS GIVEN IN DOLLARS, WITH FRANCS IN PARENTHESES)

Quartile	Experiment				
	1 (buyer)	2 (buyer)	3 (seller)	4 (seller)	5 (seller)
Periods 1-10					
Number of periods of loss	8/10	8/10	5/10	6/10	5/10
Average profit per period	-7.90 (-7.90)	-8.31 (-8.31)	-0.075 (-29.80)	-0.048 (-48.20)	0.001 (1.10)
Average RNNE profit per period ^a	4.53 (4.53)	5.70 (5.70)	0.177 (70.96)	0.060 (60.44)	0.048 (68.71)
Periods 11-20					
Number of periods of loss	4/10	2/7	3/7	2/10	7/10
Average profit per period	4.57 (4.57)	3.12 (3.12)	0.053 (21.00)	0.032 (31.60)	-0.016 (-22.40)
Average RNNE profit per period ^a	18.47 (18.47)	13.58 (13.58)	0.212 (84.85)	0.048 (48.15)	0.037 (52.68)
Periods 21-30					
Number of periods of loss				3/10	5/10
Average profit per period				0.058 (58.40)	-0.004 (-6.10)
Average RNNE profit per period ^a				0.104 (104.02)	0.090 (128.91)
Periods 31-40					
Number of periods of loss				2/5	8/10
Average profit per period				0.063 (62.80)	-0.033 (-46.80)
Average RNNE profit per period ^a				0.065 (65.34)	0.024 (33.72)

^aThe given RNNE equation is valid only for: $\bar{x} + \varepsilon \leq x_i \leq \bar{x} - \varepsilon$. Some of the winners' signals were not in this range, so no predicted RNNE profit is possible. Therefore, this average includes only periods for which the RNNE predicted profit can be calculated.

This experiment has a more severe curse than the other experiments. Unlike the other experiments, the frequency does not decline with experience.

The first two conclusions offer answers to the questions initially posed for experimental examination. The next series of conclusions reflect questions posed in an attempt

to understand why the phenomenon occurs. As was reviewed in the section above, only four theoretical models have been advanced. The first question posed was whether or not any of these four models represents the data in a statistical sense. Since the answer turns out to be negative, the next series of questions is an attempt to

FIGURE 1. PER-PERIOD PROFIT AND RNNE PREDICTED PROFITS FOR EXPERIMENT 5

Note: In periods 5, 11, 13, 20, 22, 25, 26, 31, 36, and 37, the signal is not in the interval $[\bar{x} + \varepsilon \leq x_i \leq \bar{x} + \varepsilon]$, which is the valid range for the given RNNE function. Therefore, no RNNE predicted profits are shown

identify the “best” model and to ask why it fails.

Conclusion 3: All four models (RNNE, SD, N, and PV) can be rejected as statistical representations of the data.

Evidence. Table 4 contains the results of the Chow test described in the section above. In all cases, the statistical model with parameters as restricted by the competing theoretical models can be rejected as being significantly different from the unrestricted estimates. For example, the *F* statistic for rejecting the model at a 5-percent confidence is 2.64, while the statistic for the RNNE model for buying auctions is 30.53, and for selling auctions it is 5.93.

Conclusion 4: The RNNE model is the best model of the three considered, and the N model is the worst.

Evidence. The pooled data in Figure 2 show the relationship between individual signals and bids. The visual impression favors the RNNE model. The scattered data in the upper left of the figure for the seller auctions are the bids of a small number of subjects who were (evidently) signaling for collusion.

Table 5 contains the estimated coefficients from pooled data, which can be compared with the predictions in Table 1. With the exception of the x_i coefficient, β , the standard errors tell the same stories as do the Chow tests discussed below. The param-

TABLE 4—*F* STATISTICS FOR THE HYPOTHESIS THAT PREDICTIONS OF RESTRICTED REGRESSION AND UNRESTRICTED REGRESSIONS ARE THE SAME (DEGREES OF FREEDOM; 5-PERCENT *F* VALUES)

Model	Buying auctions	Selling auctions
RNNE	30.53 (3,226; 2.64)	5.93 (3,465; 2.61)
Strategic discounting	133.84 (3,226; 2.64)	91.22 (3,465; 2.61)
Naive	341.12 (3,226; 2.64)	160.13 (3,465; 2.61)
Private value	224.87 (3,226; 2.64)	122.99 (3,465; 2.61)

FIGURE 2. PAIRS OF SIGNALS AND BIDS FOR ALL INDIVIDUALS AND ALL EXPERIMENTS

Key: Longer-dashed line shows the prediction of the N model; shorter-dashed line shows the prediction of the SD model; dotted line shows the prediction of the PV model; solid line shows prediction of the RNNE model.

TABLE 5—ESTIMATED COEFFICIENTS FOR
POOLED INDIVIDUALS
(STANDARD ERRORS IN PARENTHESES)

Experiments	α	β	γ
1-2	-22.694 (3.156)	0.998 (0.024)	0.514 (0.674)
3-5	341.658 (38.335)	0.863 (0.046)	0.255 (1.585)

eter values estimated by the regression can be rejected as being equal to those of any of the four models. The β term is close to 1, but this is predicted by all models. The intercept term, α , is closest to that predicted by the RNNE model. The γ term has such a large standard error that little can be said other than that the sign is in

agreement with both the RNNE and the SD models.

The major support for the conclusion is simply a restatement of the F statistics in Table 4. If the F statistic is taken as a measure of accuracy, then the RNNE model is always more accurate than its closest competitor, the SD model. The PV model ranks third, and the N model is the worst. The F statistics for all models were also computed for each individual. For the 35 individual data sets, the RNNE model was the best fit (lowest F statistic) for 25, and 10 of these did not differ significantly from RNNE predictions. The SD model was best for all of the remaining 10 individuals, but in all cases, the data were significantly different from the predictions of the SD model.

TABLE 6—NUMBER OF TIMES WINNER HAD HIGHEST AND SECOND-HIGHEST SIGNAL

Experiment	Highest	Second-highest	Number of periods
1 (buyer)	14	3	20
2 (buyer)	9	8	17
3 (seller)	11	3	17
4 (seller)	21	8	35
5 (seller)	25	7	40

Conclusion 5: Failure of the RNNE model is not due to a few "irrational" people. Almost all agents experienced the "curse" and bid in a manner that was consistent with "curse" behavior.

Evidence. Table 6 gives the number of times that the winning bidder had the highest signal or the second-highest signal. The game-theoretic model predicts that the individual with the highest signal will win the auction. In each experiment, more than half of the auctions were won by the subject with the highest signal. As can be seen, decisions that resulted in winning the auction were not the result of some type of impulsive move by some agent with a lower signal; nor

was it the case that bids differed so much across subjects that the fundamental game-theoretic proposition that a positive relationship exists between bids and signals is destroyed. In fact, the empirical result in Table 5 that $\beta = 1$ is strong support for that part of the theory.

Table 7 gives the number of times each agent won the auction and the number of times each agent lost money as a result of winning the auction with a bid that was too high. As can be seen, the experience happens to most individuals. Of the 28 people who won two or more auctions, 20 of them lost money 50 percent of the time or more. Of the 35 subjects, only eight never lost money.

TABLE 7—NUMBER OF WINNING BIDS SUBMITTED AND NUMBER OF TIMES LOSSES OCCURRED, BY SUBJECT AND EXPERIMENT

Subject	Experiment				
	1 (20 periods)	2 (17 periods)	3 (17 periods)	4 (35 periods)	5 (40 periods)

7					
Number of winning bids	2	3	1	3	6
Number of times lost money	1	2	0	1	5

V. Closing Remarks

One question appears to be answered clearly: a winner's curse can be observed. A presumption exists about an answer to a second question: it appears that the curse can persist over many experiences. A major puzzle remains: of the models studied, the best is the risk-neutral Nash-equilibrium model, but that model predicts that the curse will not exist.

Part of the difficulty with further study stems from the lack of theory about the behavior of common-value auctions with risk aversion. Closed-form solutions which permit researchers to estimate models of "sub-rational" behavior have not been worked out. If the effect of risk aversion is to raise the bidding function as it does in private auctions, then risk aversion together with the strategic-discounting model might resolve the puzzle; but, of course, this is only a conjecture.

APPENDIX—INSTRUCTIONS

Instructions for buyer auctions are those that were used by Kagel and Levine (1986) and can be found in the appendix to their paper. Instructions were handed out to subjects, and all examples were also on the chalkboard. After the instructions were given to the subjects, they were read aloud by the experimenter, and then the following "test" was administered.

1. Buyer A gets a signal value of \$105.00. He bids \$100.00 but he is not the high bidder. His _____ (profit/loss) is \$ _____.
2. Buyer B gets a signal value of \$75.00. She bids \$60.00 and she is the high bidder. The value of the item is \$65.00. Her _____ (profit/loss) is \$ _____.
3. Buyer C gets a signal value of \$161.00. He bids \$132.00 and he is the high bidder. The value of the item is \$131.00. His _____ (profit/loss) is \$ _____.
4. Buyer D gets a signal value of \$120.00. The value of epsilon is \$30.00. Therefore, Buyer D knows that the value of the item is between \$ _____ and \$ _____.

Instructions for the Seller Auctions [Exact Transcript]

GENERAL

This is an experiment in the economics of market decision making. The instructions are simple and if you follow them carefully and make good decisions you might earn money which will be paid to you in cash.

In this experiment we will create a market in which you will act as sellers of a commodity in a sequence of trading periods. One unit of the commodity will be auctioned off in each trading period. There will be several trading periods.

Your task is to submit written asks for the commodity. The precise value of the commodity at the time you make your ask will be unknown to you. Instead, each of you will receive some information regarding the value of the commodity which you may find useful in determining your ask. The process of determining the value of the commodity and the information you receive will be described below.

The currency in these markets is francs. Each franc is worth \$ _____ to you.

The low ask gets the item and makes a profit equal to the ask. If you do not make the lowest ask on the item, you will earn the value of the commodity.

During each trading period, you will be selling in a market in which all of the other participants are also selling. After all asks have been handed in, all signals and asks will be posed on the blackboard. We will circle the low ask and post the value of the item.

The value of the auctioned commodity (V) will be assigned randomly and will lie between 150 and 1500 inclusively. For each auction, any value within this interval has an equally likely chance of being drawn. The value of the item can never be less than 150 nor more than 1500. The values V are determined randomly and independently from auction to auction. A high value of V in one period tells you nothing about the likely value in the next period. It does not even preclude the same value of V appearing in later periods.

Although you do not know the precise value of the item in any particular trading period, you will receive information which will narrow down the range of possible values. This will consist of a private information signal which is selected randomly from an interval whose lower bound is V minus epsilon, and whose upper bound is V plus epsilon. Any value within this interval has an equally likely chance of being drawn and being assigned to one of you as your private information signal.

Throughout this experiment, the value of epsilon is 200.

PRIVATE INFORMATION SIGNALS

Although you do not know the precise value of the item in any particular trading period, you will receive information which will narrow down the range of possible values. This will consist of a private information signal which is selected randomly from an interval whose lower bound is V minus epsilon, and whose upper bound is V plus epsilon. ANY VALUE within this interval has an **EQUALLY LIKELY** chance of being drawn and being assigned to one of you as your private information signal. You will always know what the value of epsilon is.

For example, suppose that the value of the auctioned item is 762 and that epsilon is 200. Then each of you will receive a private information signal which will consist of a randomly drawn number that will be between 562 ($V - \text{epsilon} = 762 - 200$) and 962 ($V + \text{epsilon} = 762 + 200$). Any number in this interval has an equally likely chance to be drawn as your signal value.

The line diagram below shows what is going on in this example.

EXAMPLE

The value of the auctioned item is 762. This is the information each seller received, and the asks each seller made:

SELLER #	SIGNAL VALUE	ASK
1	590	703
2	756	900
3	838	947
4	634	778
5	716	775
6	847	920
7	642	825

In this example Seller #1 submitted the lowest bid, so he sells the item. His profit is the sale price 703. Seller #1 received 703 while the other sellers receive the value 762.

You will note that the value V of the auctioned item must always be between your signal value minus epsilon, and your signal value plus epsilon.

Finally, you may receive a signal value below 150 or above 1500. This merely indicates that the value V of the auctioned item is close to 150 or 1500.

Your signal values are strictly private information. **DO NOT REVEAL THEM TO ANYONE ELSE.** You are **NOT** to reveal your asks or profits, nor are you to speak to any other subject while the experiment is in progress.

You will not be told the value of V until after all the asks have been collected and posted.

No one may ask less than 0 for the item, nor may anyone ask more than 1700 (which is the maximum value of V plus epsilon). In case of ties for the low ask, we will flip a coin to decide who gets the item.

Are there any questions?

The Winner's Curse and Public Information in Common Value Auctions: Comment

By ROBERT G. HANSEN AND JOHN R. LOTT, JR.*

Do auction participants understand that auction winners tend to be those bidders who most overestimate the true value of an item? Papers by G. W. Gilley and G. V. Karels (1981), Kenneth Hendricks and Robert Porter (1988), and Stuart Thiel (1988) have presented real-world evidence that bidders act as if they understand the winner's curse. However, a recent series of papers in this *Review* and elsewhere by John Kagel and Dan Levin (1986), Douglas Dyer et al. (1989), and Kagel et al. (1989) report results from a series of sealed-bid laboratory experiments that provide evidence of individual "judgmental errors" and which lead the authors to question the general applicability of existing auction models.¹ This experimental evidence indicates that participants' behavior generally and significantly differed from what they specify as the

noncooperative (Nash) equilibrium bidding strategy for wealth-maximizing individuals in their laboratory context. More specifically, Kagel and Levin (1986) found that:

- 1) participants suffered a winner's curse in that bids often exceeded the conditional expected value of the item sold;
- 2) the high signal holder did not always win the auction;
- 3) reducing uncertainty over the item's value decreased the average price.²

One obvious question is: why does this experimental and real-world evidence produce such divergent results? In this paper, we point out that the experimental subjects in Kagel and Levin's research enjoyed limited liability for their losses and that this limited liability significantly affects the equilibrium bidding strategies for rational individuals. In fact, our goal is to show that limited liability in a common-value auction can explain each of these three judgmental errors in terms of perfectly rational behavior. Kagel and Levin misspecified the norm of rational equilibrium behavior, since they implicitly assumed unlimited liability, whereas the agents in their laboratory setting faced only limited liability.

The intuitive framework of our argument is easy to see. If a participant's cash balances during an auction series reached zero or went negative, he was no longer permitted to bid, and he was not held liable for

*Robert Hansen is an associate professor at the Amos Tuck School of Business at Dartmouth College and John Lott is a visiting assistant professor at the Anderson Graduate School of Management at the University of California at Los Angeles. We thank Gertrud Fremling and Bill Samuelson for reviewing an earlier draft of this paper, John Kagel for supplying us with the data, and seminar participants at Arizona State University, Cornell University, George Mason University, the University of Miami (Florida), Ohio State University, the Universities of California at Irvine and Los Angeles, Tulane University, the U.S. Securities and Exchange Commission, the U.S. Department of Justice, and the 1989 Public Choice/Economic Science Association Meetings. This paper was completed while Hansen was at the LEK Partnership and Lott was chief economist at the United States Sentencing Commission. Hansen received generous financial support from the Tuck Associates. Any remaining errors are our responsibility.

¹"Our experiments provide an empirical example of a market where individual judgment errors significantly alter market outcomes.... Although we reject the general applicability of Nash equilibrium bidding models..." (Kagel and Levin, 1986 p. 917). Their findings are already receiving wide attention (e.g., Colin Camerer, 1987; Richard Thaler, 1988).

²Finding 1 obviously contradicts wealth-maximizing behavior; finding 2 contradicts symmetric auction models, for in these models the high signal holder always wins; and finding 3 contradicts Paul Milgrom and Robert Weber's (1982) general theoretical result that reducing uncertainty will increase expected prices. (See James C. Cox and R. Mark Isaac (1984, 1986) for discussion on the definition of the winner's curse.)

that portion of any loss that drove his cash balances below zero; however, the auction rules stated (Kagel and Levin, 1986 p. 918) that bids in excess of one's cash balances were allowed.³ In bidding for an item of uncertain value, these cash balance rules give the subjects limited liability, in that bidders might incur losses larger than what they will have to pay. For example, in Kagel and Levin's (1986) auction series 3–8 it was possible for a bidder to receive a private information signal of \$80 even though the true value would be only \$50. If the bidder's cash balances still equalled his initial balances of \$10, a bid of anything over \$60 would make the individual's recorded loss greater than his actual loss.⁴

Lack of responsibility for large losses, at least for one-shot auctions, naturally leads to higher bidding. With unlimited liability, an increase in a bid of \$1 means that, conditional upon winning, profits are always \$1 less (losses are always \$1 greater) than without the bid increase; with limited liability, a bid increase of \$1 will mean no lower profits (no greater losses) for some states than before the bid increase. Thus, the cost of bidding higher is attenuated. This attenuation can be so strong that bids actually exceed the expected value of the item, when the expected value is calculated assuming unlimited liability. We show below that, as participants' cash balances approach zero, so that they have nothing to lose, bids approach the highest value that the item can take.

³It is of course important to note that a series of auctions was involved and that bankruptcy meant that an individual could not participate in subsequent auctions. As we point out in Section II, complete analysis of the effect that limited liability has on equilibrium bidding must account for multiperiod effects. Vernon Smith (1989 p. 160) uses the observation of bankruptcy to argue for another misspecification in Kagel and Levin's (1986) model. He argues that, while the number of bidders in their model is treated as fixed, it is actually endogenous.

⁴Kagel and Levin record profits/losses as: profits = (value of item) – (highest bid). Also, note that cash balances are \$10 for everyone only at the beginning of the auction series; profits and losses as the auctions proceed will cause balances to increase or decrease.

The experimental subjects, however, were not bidding in one-shot auctions. In a series of auctions, cash balances of the participants will not remain at their initial level; profits and losses of the participants cause cash balances to differ across participants and cause any one participant's balance to vary across auction periods. This observation leads to two further complications. First, asymmetry of cash balances leads to asymmetric bid strategies and therefore offers an explanation for result 2, that the high-signal holder will not always win the auction. As we establish below, those with low cash balances will bid higher than those with high cash balances, for the same information signal.

Second, the individual auctions within any one series cannot be considered independent. Bidding behavior in a prior auction affects the expected cash balances and optimal strategy for the next auction, so an optimal bid strategy for this prior auction must take future auctions into account. Taking this argument to the extreme, if a participant goes bankrupt in a period, he must leave the experiment and therefore forfeit the opportunity to bid in future periods. This multiperiod bankruptcy effect can, under certain circumstances, offset the one-period bid-increasing effect of limited liability. However, as we will show, the multiperiod nature of these auctions combined with limited liability in later periods can also cause bidders to take "unfair" gambles in prior periods, even though limited liability is of no use in that period itself. Given the intractability of this problem in a multiperiod context, one of the suggestions we have for future experimental research is that cash balances should be reinitialized prior to each auction in an auction series.

The following section initially ignores the multiperiod effects by focusing on one-period auctions with limited liability. This corresponds to the situation in the experimental studies, for which the theoretical analysis was limited to one-shot auctions with unlimited liability. Section II addresses the multiperiod aspects of limited liability and bankruptcy. Finally, in Section III, we test the importance of limited liability as an

explanation for this supposedly "irrational" behavior using the data employed by Kagel and Levin (1986). We also indicate certain fundamental design flaws in the experiments and what might be done to avoid these mistakes in the future.

I. A Simple Model

It would be useful to take the complete set of assumptions behind Kagel and Levin's (1986) experiments and derive the appropriate Nash equilibrium bid strategies. However, Kagel and Levin did not even solve for the complete equilibrium given unlimited liability, and their value and probability assumptions are not amenable to easy analysis.⁵ Limited liability, asymmetric cash balances, and a multiperiod context make their model even more intractable. For these reasons, we instead chose to analyze a simple discrete model in detail. The important results, however, are clearly (but only at considerable analytic expense) generalizable to more complex situations. Besides illustrating the effects of limited liability in Kagel and Levin's experiments, such a simple model of real-world auctions with limited liability should be interesting in and of itself. As we discuss below, one such application of the model is to auctions in which the seller guarantees the value.

Assume that two risk-neutral bidders compete in a one-shot auction for an item that has a value of either 0 or X . A statistical information service independently (conditional on item value) provides each bidder with one of two possible messages (message-1 and message-2) concerning item value. All calculations to follow will be based on the following probabilities:

prior probability: $\Pr(\text{value} = X) = p$;
posterior probability: $\Pr(\text{value} = X | \text{messages } i \text{ and } j) = p_{ij}$;

⁵The basic problem arises because of two conflicting assumptions: private information signals are uniformly distributed over $(X_0 - \varepsilon, X_0 + \varepsilon)$, where X_0 is the true value, but X_0 must be in (\underline{X}, \bar{X}) , the range of true values. Information signals less than $(\underline{X} + \varepsilon)$ or greater than $(\bar{X} - \varepsilon)$ are difficult to interpret because of endpoint problems.

conditional message probabilities: $\Pr(\text{opponent receives message-}i \text{ when message-}j \text{ received}) = m_{ij}$.

We further assume that message-1 is the "good" message, so that $p_{11} > p_{12} = p_{21} > p_{22}$.⁶

As a first step in the analysis, note that equilibrium bid strategies for the one-shot auction with unlimited liability are:⁷

$$(1) \quad b(m) = \begin{cases} \text{if } m = \text{message-2,} \\ b(m) = p_{22}X \\ \text{if } m = \text{message-1,} \\ \text{bid randomly in the interval} \\ (p_{22}X, m_{11}p_{11}X + m_{21}p_{22}X) \\ \text{according to the bid} \\ \text{distribution function} \\ F(b) = \frac{m_{21}(b - p_{22}X)}{m_{11}(p_{11}X - p_{22}X)}. \end{cases}$$

Derivation of this equilibrium follows from two observations: 1) contingent upon message-2, bidders must have zero expected profit and 2) contingent upon message-1, bidders must randomly make bids over some interval such that each bid yields the same expected profit. Note that bidding strategies are symmetric in this equilibrium, so that the high signal holder always wins the auction. Also, expected profits conditional on message-1 are positive; hence, the expected price must be less than the prior expected value of the item, pX .

The next step is to introduce starting cash balances and limited liability. Let c be each individual's initial cash balance and assume that the participant's liability is limited to c and that $c < p_{22}X$. Equilibrium with limited

⁶For simplicity, we have not derived these probabilities from the more fundamental probabilities of messages conditional on the state that occurs.

⁷Donald Hausch (1986) has derived the equilibrium for these assumptions for use in another context.

liability is then as follows:

(2) $b(m)$

$$= \begin{cases} \text{if } m = \text{message-2,} \\ b(m) = X - \left(\frac{1 - p_{22}}{p_{22}} \right) c \\ \text{if } m = \text{message-1,} \\ \text{bid randomly in the interval} \\ (X - [(1 - p_{22})/p_{22}]c, b^*) \\ \text{according to the bid} \\ \text{distribution function} \\ F(b) = \{m_{21}c[(p_{21} - p_{22})/p_{22}] \\ - m_{21}[p_{21}(X - b) - c(1 - p_{21})] \\ \times m_{11}[p_{11}(X - b) - c(1 - p_{11})]^{-1} \end{cases}$$

where

$$(3) \quad b^* = X - [c/(m_{11}p_{11} + m_{21}p_{21})] \\ \times [m_{21}[(p_{21} - p_{22})/p_{22}] \\ + m_{21}(1 - p_{21}) + m_{11}(1 - p_{11})].$$

As for the previous equilibrium, this bid function is derived by noting that expected profits conditional on message-2 must be zero and that profits conditional on message-1 must be the same for every bid included in the mixed strategy. The upper bound for the bid distribution is found by setting $F(b) = 1$. It is important to note that, as c decreases, the entire bid distribution moves toward the highest possible item value, X . Indeed, if $c = 0$, equilibrium calls for both bidders to bid X regardless of messages received. Thus, as bidders have less to lose, they become more aggressive in their bidding. Of course, as this occurs, bids will exceed the conditional expected value of the item.

Consider next what happens in the limited-liability case as uncertainty over item value is reduced. According to the general model of Milgrom and Weber (1982) and as is consistent with the unlimited-liability bidding equilibrium of Kagel and Levin, reducing uncertainty should increase expected

prices.⁸ An extreme example shows that this result need not hold under limited liability. Suppose that cash balances are arbitrarily close to zero for both participants, so that the equilibrium bids are also arbitrarily close to X no matter what the messages are. The expected price is therefore in the neighborhood of X . If we now remove all uncertainty, so that participants know whether an item's value is either 0 or X , bids will be either 0 or X , depending upon the message received.⁹ Expected price will then be the average of 0 and X , which is (considerably) less than the expected price with uncertainty and limited liability. More generally, with limited liability and less-extreme reductions in uncertainty, we expect the effect on expected prices to be ambiguous: the Milgrom and Weber effect works against the limited-liability effect. However, the limited-liability effect is stronger the lower are cash balances, so that the expected price will be more likely to fall with a reduction in uncertainty the lower are cash balances.

We have now established that Kagel and Levin's (1986) results 1 and 3 can be perfectly consistent with rational maximizing behavior. What remains to be shown is that, in a limited-liability context, the high signal holder might not always win the auction. The intuition is as follows: if cash balances are not equal across bidders, the equilibrium will also be asymmetric, with bids conditional upon the same message differing across participants. Bidders with low cash

⁸Notice that an extreme form of this result holds for our unlimited-liability model. With uncertainty, the expected price is less than prior expected item value; without uncertainty, expected price equals expected item value.

⁹With zero cash balances, equilibrium is arbitrary. With cash balances close to zero, the only equilibrium will be to bid 0 or X , depending upon the message received. Also, it is interesting to note that the zero-cash-balance equilibrium corresponds to a bidding equilibrium where the seller guarantees the value to be X . In that case, the seller always receives X as the high bid but must reimburse X if the value turns out to be zero. The expected price less the expected warranty is the prior expected value, pX . Giving a warranty is therefore similar, in terms of its revenue effects, to providing information.

balances will bid higher and win more auctions than participants with high cash balances.

To illustrate this formally, we take another extreme example: Suppose bidder A has a zero cash balance while bidder B has a cash balance of c . Then an equilibrium is as follows:

$$(4) \quad b_A = p_1 X + \alpha$$

$$(5) \quad b_B = p_1 X$$

where p_1 is the probability of the value equalling X conditional only on message-1 and α is the lowest bid increment. Given b_B , bidder A has no incentive to bid higher, since he always wins already; bidder A also has no incentive to bid any lower, for that would entail losing some profitable auctions. Given b_A , participant B would not bid higher (conditional on either message), because that would entail paying more than the expected value if he should win (which he would).

For this example, the zero-cash-balance participant always wins, even in the case in which he is not the high signal holder. In addition, the high-cash-balance bidder has zero expected profits; competing against someone who has nothing to lose cannot be profitable.

II. Multiperiod Effects

The main implication of a multiperiod setting is that equilibrium bidding strategies cannot be found for each separate auction by simply maximizing a bidder's expected profits for that auction alone. Instead, the objective for a participant must be to maximize the expected end-of-series cash balance, and the instruments available for achieving this objective will be the bids in all the auctions. To get an idea of the complexity that such analysis entails, note that an optimal first-auction strategy must take into account subsequent auctions. These subsequent auctions will necessarily involve asymmetric cash balances, and bidding behavior in the first auction will necessarily affect all participants' expected cash bal-

ances in subsequent auctions. Thus, to assess the profitability of bidding a little higher in the first auction, a bidder must account for how that will affect his and his competitors' cash balances and bid strategies conditioned on cash balances for later auctions. A simple example using two sequential first-price sealed-bid auctions can demonstrate the "irrational" implications of limited liability. Specifically, the example establishes that *limited liability can cause bidding in excess of expected value in initial auctions even if bankruptcy could never occur in that auction under unlimited-liability Nash equilibrium*.¹⁰

Suppose two risk-neutral bidders compete in a series of two auctions. In each auction, the item for sale has a value of either zero or \$20, with each event having a probability of 0.5. With unlimited liability, each bidder will bid the expected value of \$10 in each of the two auctions. (Ties are randomly broken.) Alternatively, suppose that each bidder begins the auction series with \$15 and that losses are limited to this amount. To see how bidding behavior changes with limited liability, suppose that bids remain at \$10 in the first auction. If the value turned out to be \$20 in the first auction, cash balances entering the second auction are \$15 and \$25, and each bidder will find it optimal to bid \$10 in the second auction. If, however, the value had turned out to be zero in the first auction, cash balances are \$15 and \$5 entering the second auction. Now the participant with a \$5 cash balance will be willing to bid more than \$10 in the second auction: a bid of \$10 gives him a 50-percent chance of ending with an expected cash balance of \$7.50 (either zero or \$15, with each equally likely) and a 50-percent chance of ending with his current bal-

¹⁰Prior reviews of our paper have focused on Kagel and Levin's initial auctions, in which cash balances are indeed high enough to make bankruptcy unlikely (but not impossible) under unlimited-liability equilibrium. The conclusion drawn is that limited liability is therefore unlikely to be a serious problem. However, as our example shows, the prospect of lower cash balances and bankruptcy in future auctions forces higher bidding even in the initial auctions.

ance of \$5. For example, a bid of \$10.01 gives him the certainty of ending with an expected cash balance of \$7.495. The low-cash-balance bidder effectively has a higher valuation and will win the second auction.

Was the initial assumption of \$10 bids in the first auction accurate? A simple analysis shows that bids of \$10 in the first auction imply expected end-of-series balances for each participant of \$15.625, more than they begin with. It is counterintuitive that profits should remain in a symmetric game such as this, and indeed, one can show that bids in excess of \$10 in the first auction are profitable. A bid of \$11.67 in the first auction eliminates any profit from the series as a whole (ending expected cash balances are \$15) and is in fact the equilibrium bid for each participant in the first auction.¹¹ Essentially, participants do not weigh losses in the first auction as heavily as they would under unlimited liability, because there is some chance that one dollar less carried into the second auction will not affect ending cash balances whatsoever (in bankruptcy, the seller takes all there is, be that \$5 or \$10).

To summarize, limited liability causes bidding in excess of expected values, even in auctions in which cash balances are initially high enough to eliminate the possibility of bankruptcy. (Interestingly, in our simple example, overbidding occurs only in the first auction, for in the second auction, the low-cash-balance participant wins by bidding $10 + \epsilon$.) It is therefore incorrect to treat the auctions of a series as being independent, and it is incorrect to argue that limited liability is not important overall on the basis of cash balances and bankruptcy probabilities in the initial auctions.

III. Reviewing the Evidence

Possibly Kagel and Levin's (1986) most important evidence is provided by their table 2, which implies overbidding in general and

a definite negative relationship between the number of bidders participating in an auction and the average "actual" profits from that auction. Their results, which are reproduced here in columns 2 and 3 in our Table 1, show their reported values for the average "actual" profits and the average "actual" profits as a percentage of profits that would occur under a risk-neutral Nash equilibrium (RNNE) by auction series. While Kagel and Levin use the term "actual" average profits, a more appropriate description is the *hypothetical* average profit that would have been obtained from the private-information bids had those actually been the effective bids. In auction series 3–8, Kagel and Levin employed a two-tier set of auctions in which a separate public-information auction was also performed after the private-information auction had been conducted. A coin flip determined whether the bids from the public- or the private-information auctions were the effective bids. If, as column 2 assumes, the bidders' private-information bids had always been the effective bids, several bidders who participated in all the auctions in experiments 3-large, 4, 5, and 8-large would have faced bankruptcy prior to the end of the auction series.

On this matter of limited liability, Kagel and Levin (1986 p. 896) state that, when an individual's "balances went negative, he was no longer permitted to bid; he was paid the \$4.00 participation fee and free to leave the experiment." In the actual auctions, individuals could not lose more than their initial starting balance of either \$8.00 (series 1 and 2) or \$10.00 (series 3–8). However, in calculating the hypothetical balances shown in columns 2 and 3, Kagel and Levin neither removed an individual when his hypothetical balances fell below zero nor truncated the bidder's losses at zero cash balances. They removed bidders from the sample only when the bidder's cash balances based on the effective bids reached zero, and not based on the hypothetical balances that they were calculating in column 2. Their accounting procedures resulted in larger recorded losses than it was possible for individuals ever actually to realize. Columns 4 and 5 then show what average profits would have been if losses had been stopped at

¹¹With a bid of \$11.67 in the first auction, expected cash balances will be either \$23.33, \$6.665, \$15, or \$15 at the end of the second auction, with equal chances of each.

TABLE 1—REVIEWING THE EVIDENCE ON AVERAGE PROFITS PER AUCTION WITH PRIVATE-INFORMATION BIDS

Auction series (number of periods) (1)	Kagel and Levin (1986)		Our calculations		Size of the last period's profit or loss (6)	Average profit up until last auction (standard deviation) ^a (7)	Percentage change in the last period's profits from (7) (8)	Significance level for test that (6) differs from (7) ^b (9)	Average profit up until last auction as percentage of RNNE (10)

^aBased on our calculation of actual balances.

^bThe null hypothesis is that the value from column 6 was drawn from the same distribution as those in column 7. Levels of significance for a one-tailed *t* test are shown.

zero cash balances based on the effective bids¹² and if losses or gains had been calculated in terms of both effective and non-effective private-information bids.¹³ While largely similar to Kagel and Levin's numbers, the average losses are reduced or eliminated for four of the auction series using 5-7 bidders (series 3-large, 4, 5, and 8-large), thus slightly weakening their results.¹⁴

¹²This seems to be the correct procedure because: 1) it is consistent with when bidders are removed from the auction and 2) it constrains their losses to what their true maximum losses can be. It is interesting to note that redoing Kagel and Levin's (1986) table 7 in a similar manner raises the hypothetical profits from public-information bids as a percentage of RNNE by about 6 percent.

¹³In doing these calculations, we limit losses to an individual's cash balances even when the bid is not an effective bid (because of the concomitant public-information auction). This seems to us to be more relevant than using bids that are not effective and not limiting losses, as Kagel and Levin (1986) do. An alternative is to limit losses and use only the effective private-information bids. Such a limit further increases profits for some auction series and further reduces the difference between the large- and small-numbers cases.

¹⁴We were able to replicate all of the results that Kagel and Levin (1986) reported in their table 2 and obtained very similar estimates to theirs in the other cases.

In examining Kagel and Levin's data, we noted another interesting aspect of their experiment. At first glance, the length of each auction series seems random, with experiments 7 and 8 lasting 37 periods and some, such as 1 and 2, lasting only 18 periods. However, as indicated in column 6 of Table 1, all five of the experiments involving a small number of bidders ended on a profit-making bid, while five of the six experiments involving a large number of bidders ended on a losing bid.¹⁵ Not only did the auction series that Kagel and Levin predicted should be profitable stop on winning bids and those experiments that they predicted would lose money stop on losses, but as column 8 indicates, they tended to stop when unusually large gains or losses occurred.

In the experiments involving a large number of bidders, the auction series ended with losses averaging 1,643 percent less than

¹⁵Even in the one case in which a series with a large number of bidders (7-large) was ended on a win, the percentage change in profits from the average wins up until the last auction was the smallest of any of the 11 changes shown in Table 1.

the average profits up to that point.¹⁶ The null hypothesis that each individual series with a large number of bidders (1, 3-large, 4, 5, 7-large, and 8-large) ended with an outcome drawn from a distribution with an average equal to the prior average was rejected at the 0.04, 0.07, 0.05, 0.12, 0.45, and 0.06 levels, respectively, in one-tailed t tests. We can strongly reject the hypothesis that all six series ended on an outcome equal to the prior average profits at the 0.0000004 level with a one-tailed t test.¹⁷ The experi-

¹⁶This bias can only be explained in one of the six cases with a large number of bidders (3-large) as resulting from one of the bidders going bankrupt so that there was no longer the requisite number of bidders to qualify as a case with a large number of bidders. In that instance, when the fifth bidder went bankrupt, the large-number-of-bidders auctions series ended, and the auction series with a small number of bidders started. The experiments should have been set up so that the series were never constrained to end on a loss. However, this does not explain why the other auctions with large or small numbers of bidders ended in the systematic manner that they did (see footnote 18 for a related discussion).

The bias obviously cannot be explained by other variables that were under the experimenters' control, such as by any systematic variations in ϵ . In experiment 7-large, ϵ was lower at the end of the auction series than at the beginning; in auction series 1, 2, and 3-small, ϵ started and ended on the same values, and in auction series 5 and 6, ϵ was declining at the end of the auction series. In the remaining auctions, ϵ was increasing at the end of the auction series.

Equally important, the second-to-last period's profits or losses do not suggest any systematic variations. In four of the auctions with small numbers of bidders, the second-to-last period's profits were less than the average profits up until that last auction, and in two of the cases, the reverse was true. In the auctions with large numbers of bidders, the second-to-last period's profits were less than the average profits up to that point in three cases, and in the other two cases, the reverse was true. This provides some evidence against claims that there were some underlying trends in the series.

¹⁷An interesting feature of the data for the series with a large number of bidders was that auction series 1 ended on the largest loss of the 18 auctions in that series, auction series 3-large ended on the largest loss of its 11 auctions, auction series 4 ended on the second-largest loss of its 25 auctions, auction series 5 ended on the second largest loss of its 26 auctions, auction series 8-large ended on the second largest loss of its 14 auctions, and auction series 7-large (the only one to end on a profit-making bid) ended on the ninth-smallest value out of 19 auctions.

ments involving a small number of bidders ended with a profit that was averaging 124 percent higher than the average profit in all the preceding auctions.¹⁸

The importance of this can be seen by looking at column 7 in Table 1. Dropping the results from the last auction in each series alters the previous findings, with the average profits rising for all of the auctions with large numbers of bidders and falling for all but one of the auctions with small numbers of bidders. *The average profits per auction for the auctions with large numbers of bidders changes from -25 cents in Kagel and Levin's results to +43 cents here.*¹⁹ While the average profits as a percentage of RNNE are still lower for the cases with large numbers of bidders, the relationship is no longer as systematic as claimed by Kagel and Levin and largely owes itself to three of the 11 series: 3-small, 3-large, and 8-large. While acknowledging that removing those three series from the sample may be discarding valuable information, it is interesting to note that the average profits as a percentage of RNNE for the remaining four series involving 3-4 bidders is 52.8, and it is 31 for the four remaining series for 5-7 bidders.²⁰

¹⁸The series with a small number of bidders showed a similar, though much less pronounced, pattern to that noted in footnote 15; auction series 2 ended on the third-largest gain of the 18 auctions in that series, auction series 6 ended on the sixth-largest gain of its 31 auctions, auction series 7-small ended on the eighth-largest gain of its 19 auctions, and auction series 8-small ended on the fifth-largest gain of its 23 auctions. However, auction series 3-small, which already had the highest average profits, ended on the eight-largest gain of its 14 auctions.

¹⁹Since most of the truncations of the losses occurred during the final auction period, most of the change between columns 2 and 7 would have occurred even if we had not done the transformation shown in column 4.

²⁰Kagel has informed us that the rule used to determine when to end each auction series was that each series would last two hours. A possible explanation for the above pattern might be that this foreseen last period caused the bidders to behave in a systematically biased manner, depending upon whether they were part of a large or a small group of bidders. Why these systematically different effects exist is unclear. Since the same participants are often used in one long experi-

While the preceding indicates that Kagel and Levin's evidence is not quite as strong as they claim, the most important question still remains: to what extent can the overall results be explained by limited liability? In order to answer this question, we reran the specification shown in their table 4 across the entire sample.²¹ (For the moment, we will not try to control for the bias over when the auction series were ended.) Kagel and Levin (1986 p. 899) argue that the bid should be a function of the private signal, the dispersion in possible values that the private signal can take from the true value (ϵ), the number of bidders, and an adjustment for how the bid should vary in accordance with the risk-neutral Nash equilibrium (Y).

Fortunately for our purposes, it was also possible to obtain the level of each bidder's cash balances prior to the bids. Our earlier discussion suggests that, if limited liability is important, bids should be negatively related to cash balances. Those who face small losses because of constrained cash balances should increase their bids. The potential importance of cash balances may be quite

large, since cash balances are less than ϵ for 80 percent of the 1,101 bids and the median is \$6.84 (or 38 percent) less than the median value of ϵ . Importantly, theory also suggests that cash balances should affect bidding differentially according to the private signal received (note that in the equilibrium of Section II, the effect of cash balances varies with the message). Thus, we have included an interactive term between a bidder's cash balances and his private-information signal.

In addition, there was one other source of problems in Kagel and Levin's experimental setup. While the bidders knew the minimum and maximum possible values that the true value could equal, the private signal was less than the minimum value that the true value could take in 35 cases and was greater than the maximum value in 25 cases. Obviously, those who know that their private signal is greater than the maximum possible true value should discount their bid (as compared to the RNNE), while those who know the reverse is true will increase it. In addition, in those cases, ϵ could provide a biased estimate of the risk associated with the bid.²² We sought to control for these effects by using two dummy variables to indicate when the private signal is outside these possible values.

Using ordinary least squares, the reestimated regressions from Kagel and Levin's table 4 after controlling for the level of cash balances prior to each bid are

$$\begin{aligned}
 (6) \quad & \text{private-information bid} \\
 & = 0.9809(\text{private signal}) \\
 & \quad (438.92) \\
 & + 0.2592(\text{number of bidders}) \\
 & \quad (1.5151) \\
 & - 0.5644 \epsilon \\
 & \quad (17.13) \\
 & - 0.07311(\text{cash balances prior to bid}) \\
 & \quad (2.512) \\
 & - 0.16 \\
 & \quad (0.13)
 \end{aligned}$$

iment involving both small and large number of bidder auctions, even if the bidders know when the entire auction will end, they can only tell when one of the two types of auctions will end. To put it differently, auction series 7 lasts 37 periods, of which the first 19 are for the case with a small number of bidders. All six bidders employed in groups of four during the first 19 auctions continue to be employed altogether in a group of six for the remaining 18 auctions. Even if these bidders genuinely face some type of last-period effect at the 37th auction, why would the bidders perceive the 19th auction as distinct from the previous 18 auctions? Whatever the reason, any evidence of the winner's curse depends upon the inclusion of these last periods in the auction series.

²¹Unlike Kagel and Levin (1986), we have run our regressions over the entire data set. Kagel and Levin's justification for excluding the data near the extreme values that the item can take is that their bidding equilibrium only holds in the interior range. Since we believe that their bidding model is incorrect, we also believe that it would be incorrect to delete observations on the basis of that model. Our regressions are consistent with their table 2, which provides their strongest evidence, in which they do not exclude these observations. We also ran all of our regressions only over the same observations employed by Kagel and Levin, but this did not qualitatively alter our findings with respect to the cash-balance variables.

²²Because of this truncation, large values of ϵ will not seem to elicit very large reductions in the price due to risk, simply because the true value of ϵ is not as large as that measured.

($R^2 = 0.994$, sum of squared residuals = 62,129.3, $N = 1,101$) and

(7) private-information bid

$$\begin{aligned}
 &= 0.984 (\text{private signal}) \\
 &\quad (446.48) \\
 &+ 0.1367 (\text{number of bidders}) \\
 &\quad (0.851) \\
 &- 0.6074 \varepsilon \\
 &\quad (19.55) \\
 &+ 0.014 Y \\
 &\quad (12.38) \\
 &- 0.0773 (\text{cash balances prior to bid}) \\
 &\quad (2.83) \\
 &- 0.73 \\
 &\quad (0.63)
 \end{aligned}$$

($R^2 = 0.995$, sum of squared residuals = 54,505.9, $N = 1,101$), where the absolute t statistics are shown in parentheses. Two features of these results immediately stand out. First, the individual bidders' cash balances are always significantly negatively related to the level of the bid, and second, inclusion of the cash balances significantly reduces both the size of the coefficient for the number of bidders and its significance.

When an interactive term for cash balances and the private signal is added in these two specifications, the net effect of cash balances on the size of the bid is negative for values of the private signal greater than 75.7 and 60. These critical values are only about one-half the private-information signal's mean value of 136.3. While the coefficient on the number of bidders is always positive and significant at the 0.10 level in single-tailed t tests when we do not control for cash balances, it is significant at that level in only two of the four regressions that employ cash balances.²³ In-

clusion of the cash-balance terms reduces the coefficients on the number-of-bidders variable by between 10 percent and 44 percent, with an average decline of 25 percent.

Not only is the variable for cash balances statistically significant, it is also economically important, at least compared with the number-of-bidders variable. A one-standard-deviation increase in a bidder's cash balance (\$8.26) implies that the average bid will decline by between 42 and 64 cents using equations (6) and (7). Similarly, a one-standard-deviation increase in the number of bidders (1.37) implies an increase in the size of the bid of between 19 and 36 cents. To put it in slightly different terms, using equation (7), the number of bidders would have to increase from 3 to 7.68 in order for the number-of-bidders variable to offset a one-standard-deviation increase in cash balances (note that the number of bidders in the data only ranges from 3 to 7).

When the dummy variables for whether the private signals were greater than the maximum possible true value or less than the minimum possible value are included, their effects are quite significant. The coefficients for those dummy variables indicate that the bids are typically decreased by almost \$4 when the private signal is greater than the maximum possible true value and increased by almost \$23 when the reverse is true. The inclusion of these two terms increases the significance and the size of the coefficients for ε and the number of bidders and greatly reduces the significance and size of Y .

As noted earlier, the periods on which the auctions series were ended differ significantly from prior periods. The preceding regressions were then reestimated without those last periods and are reported in Table 2. The results coincide closely to those reported above in all but two respects. The most obvious differences is that the coefficients for the number of bidders are both from 10-percent to 30-percent smaller and less likely to differ significantly from 0, once those last periods are removed from the sample. In only four of the eight regressions is the coefficient significant at the 0.10 level in a single-tailed t test, and that is true for

²³Exclusion of the intercept term in the regressions shown in Table 2 results in the number-of-bidders variable being significant at the 0.10 level for a single-tailed t test in only two of the five regressions that control for cash balances. Excluding the intercept, however, has almost no effect on the other variables.

TABLE 2—REGRESSIONS EXCLUDING THE LAST AUCTION IN EACH SERIES: ENDOGENOUS VARIABLE IS THE LEVEL OF PRIVATE-INFORMATION BIDS
(ABSOLUTE *t* STATISTICS IN PARENTHESES) (*N* = 1,046)

Specification	Private signal	Number of bidders	Cash-balance prior to bid	Cash-balance \times private-signal interaction	ϵ	<i>Y</i>	Private signal > maximum value possible	Private signal < minimum value possible	Constant	<i>R</i> ² [sum of squared residuals]
1	0.9822 (437.1)	0.2865 (1.682)	—	—	-0.5750 (17.49)	—	—	—	-1.35 (1.2)	0.994 [59,390.7]
2	0.9817 (434.5)	0.2081 (1.193)	-0.0627 (2.009)	—	-0.5571 (16.37)	—	—	—	-0.29 (0.2)	0.995 [59,161.2]
3	0.9851 (462.8)	0.1840 (1.147)	—	—	-0.6214 (19.93)	0.0014 (11.68)	—	—	-0.52 (0.5)	0.995 [52,513.8]
4	0.9846 (460.6)	0.0975 (0.593)	-0.0689 (2.349)	—	-0.6019 (18.68)	0.0014 (11.74)	—	—	-0.64 (0.5)	0.995 [52,236.6]
5	0.9920 (520.2)	0.2766 (1.973)	—	—	-0.6720 (24.53)	0.0004 (3.36)	-4.005 (3.16)	22.891 (17.79)	-1.50 (1.5)	0.996 [39,952.4]
6	0.9917 (516.2)	0.2264 (1.573)	-0.0400 (1.541)	—	-0.6605 (23.28)	0.0004 (3.43)	-3.960 (3.12)	22.770 (17.68)	-0.78 (0.8)	0.996 [39,861.2]
7	1.0050 (185.8)	0.2837 (1.635)	0.1426 (2.694)	-0.0018 (4.77)	-0.5430 (16.07)	—	—	—	-3.70 (1.3)	0.995 [57,892.6]
8	1.0030 (196.3)	0.1599 (0.976)	0.0913 (1.821)	-0.0014 (3.92)	-0.5896 (18.34)	0.1360 (11.38)	—	—	-2.1 (1.5)	0.995 [51,473.5]

only two of the five cases when we control for cash balances. In fact, the removal of the intercept term for the regressions shown in specifications 7 and 8 in Table 2 actually causes the coefficients on the number of bidders to switch signs and equal -0.04 and -0.19. The results in Table 2 also diverge from the earlier ones in that the coefficients for cash balances (when they appear alone—specifications 2, 4, and 6), while they are always still significant and negative, are associated with larger *P* values (greater probability of type-I error) than they were previously. The net effect of cash balances is still negative at relatively small values of the private-information signals of \$79 and \$65 for specifications 7 and 8 in Table 2.

We also noted in Table 1 that the results there were sensitive to the inclusion of a few of the auction series. If our discussion of cash balances is correct, the exclusion of series 3-large and 8-large should weaken the importance of the cash-balance term, since bidders in those two auctions suffered unusually large losses and thus faced greater reductions in liability in the preceding auctions. Rerunning the specifications from Table 2, excluding series 3-large and 8-large (but without dropping the last auctions in the remaining series), the coefficients for the cash-balance terms were still always significant and negative, but were less so than for the cases shown in Table 2.

Even more interesting, however, was the effect that this change had on the coefficient for the number-of-bidders variable. The coefficient was now negative in seven of the eight specifications and was negative and significant at the 0.15 level for a single-tailed *t* test in five cases. The *t* statistic for the single case in which the coefficient was positive was only 0.068. These results are important, since a negative coefficient is exactly what the risk-neutral Nash equilibrium predicts. Since the likelihood that a bidder will suffer the winner's curse increases with the number of bidders that he outbids, bidders facing a large number of bidders adjust their bids downward accordingly. The fact that their results do not hold over 9 of the 11 auction series at least indicates that some caution is necessary in accepting any claims of the winner's curse being a function of the number of bidders.

As an alternative to controlling for cash balances, we replaced cash balances with a variable equal to ϵ minus cash balances, but with all negative values set equal to zero. The logic here is that if cash balances were greater than ϵ and individuals bid the expected value of an item, they would not create a limited-liability problem. Therefore, running cash balance by itself should bias downward the effect of the coefficient, since we do not expect cash balances greater than ϵ to have any effect on the level of the

bids. These changes left largely unaltered both the sizes and significance levels of the cash-balance effects previously discussed.²⁴

One general objection to our empirical work is that, despite using the bidder's cash balances immediately preceding his bid, the causation does not run from low cash balances to higher bids, but instead, individuals who bid too high tend to have low cash balances. In order to control for these individual-specific characteristics, which may account for the earlier importance of the cash-balance effect, we reran the earlier specifications shown in Table 2 (though over the entire sample) including a dummy variable to denote each of the individual bidders (bidder number 7 in auction series 8-large is represented by the intercept). The corresponding regressions (shown in Table 3) produce somewhat mixed results. While the effect of cash balances on the level of bids is always negative, the coefficients in specifications 2 and 4 in Table 3 are significant at only the 0.127 and 0.109 levels, respectively, for a one-tailed *t* test. In specifications 5 and 6 of Table 3, where the interaction between cash balances and private signals is allowed, the cash-balance and interaction coefficients are both highly significant. The net effect of cash balances becomes negative at values of the private signal greater than 88 and 92. Also, the coefficients for the number-of-bidders variable range from only 37 percent to 93 percent of the size of those found by Kagel and Levin and are significant at the 0.10 level for a one-tailed *t* test in four of the six regressions.²⁵

Finally, Kagel and Levin's table 2 suggests that the bidder with the highest private signal only wins the auction 71 percent of the time. The question is whether know-

ing what the lowest bidder's cash balances were will help explain the probability that he will win the auction. To test this, we ran a dummy variable indicating which bidder won the auction in each series on two new variables: 1) the difference between the bidder with highest private signal in each auction and the private signal of each bidder in that series ("difference in an auction's private signals") and 2) the difference between the bidder with the highest cash balance in each auction and the cash balance of each bidder in that series ("difference in an auction's cash balances"). (These variables are zero for the bidders with the highest private signal or cash balances in any particular auction.) However, as demonstrated in Tables 2 and 3, it is not just the difference in cash balances that is relevant, but also their level. Therefore, we estimated separate regressions by multiplying the "difference in an auction's cash balances" variable in each successive regression with a different dummy variable according to whether the cash balances were less than \$2, \$4, \$6, or \$8.

The results (shown in the regressions in Table 4) provide some support for our hypothesis. The Probit regressions show that the effect of the "difference in an auction's private signal" variable is consistently significant. However, only the interaction term for "difference in an auction's cash balances \times the dummy for when cash balances are less than \$2 is significant at the 0.10 level for a single-tailed *t* test.²⁶ One possible explanation for the cash-balance variable's relatively low levels of significance is that when cash balances are low for any individual bidder in an auction they tend to be low

²⁴ We also tried using a variable equal to cash balances divided by ϵ and obtained similar results.

²⁵ We note here another effect possibly confounded with the effect of cash balances. Suppose an individual loses money in an initial auction and therefore bids high in the following auctions (in accordance with his low cash balance). The cash-balance effect therefore becomes confounded with the individual dummy variable. This multicollinearity should reduce the significance level of the cash-balance variable.

²⁶ While the effects of the interaction term are not statistically significant, for cash values less than \$4, \$6, and \$8, the *t* statistics are successively smaller. Regressing the dummy variable for the auction's winner on the "difference in an auction's private signals" and "difference in an auction's cash balances" without the interaction effect reveals that the effect of the private signal is relatively unchanged but that the effect of cash balances is only significant at the 0.125 level for a one-tailed *t* test. However, this indicates that continuing the interaction terms for still higher levels of cash balances would eventually increase the level of significance.

TABLE 3—REGRESSIONS TAKING ACCOUNT OF THE INDIVIDUAL CHARACTERISTICS OF BIDDERS:
ENDOGENOUS VARIABLE IS THE LEVEL OF PRIVATE-INFORMATION BIDS.
(ABSOLUTE *t* STATISTICS IN PARENTHESES) (*N* = 1,101)

Specification	Private signal	Number of bidders	Cash balance prior to bid	Cash-balance \times private-signal interaction	ϵ	<i>Y</i>	Constant	Adjusted <i>R</i> ² [sum of squared residuals]
1	0.9669 (410.0)	0.5097 (2.2095)	—	—	-0.6416 (20.01)	—	5.3248 (2.7766)	0.996 [44,123.7]
2	0.9670 (409.5)	0.5145 (2.2304)	-0.0363 (1.1483)	—	-0.6303 (18.62)	—	5.4317 (2.8285)	0.996 [44,077.7]
3	0.9716 (436.3)	0.2577 (1.1945)	—	—	-0.6719 (22.43)	0.0013 (12.72)	6.0127 (3.3653)	0.996 [38,226.5]
4	0.9717 (435.9)	0.2629 (1.2186)	-0.0389 (1.2392)	—	-0.6541 (20.81)	0.0013 (12.73)	6.1311 (3.4276)	0.996 [38,170.6]
5	0.9873 (196.1)	0.6070 (2.6465)	0.1317 (2.8581)	-0.00149 (4.5376)	-0.6243 (18.60)	—	1.9536 (0.9524)	0.996 [37,669.9]
6	0.9872 (210.0)	0.3410 (1.5828)	0.1052 (2.1170)	-0.00115 (3.7285)	-0.6541 (20.81)	0.0013 (12.42)	3.4330 (1.7885)	0.996 [39,861.2]

for all the other bidders as well and thus do not greatly affect the relative ranks of bids within any given auction. After the highest cash balance in each auction is removed, the average value for the "difference in auction's cash balance" variable is only \$8.49.²⁷

²⁷There is also evidence that the values of ϵ were not independent of the auction results. At first glance, the changes in ϵ seem to be random with $\epsilon = 12$ lasting anywhere from 6 to 18 auction periods, depending on the auction series; likewise $\epsilon = 30$ ranges from 6 to 12 periods, and $\epsilon = 18$ ranges from 8 to 16 periods. The problem is that if ϵ tends to be relatively large for the cases with large numbers of bidders, limited liability would tend to be more of a problem for these cases, and it would appear that those bidders were behaving relatively less "rationally." Likewise, if ϵ only tended to be low when cash balances were also low and tended to be high when cash balances were high, the limited-liability problem would be present a larger percentage of the time. To examine this, we regressed ϵ on the 2^K set of variables for the bidder's cash balances prior to that auction, the square of that value, and a dummy variable which equalled 1 when the number of bidders was greater than or equal to 5. The coefficients consistently showed that both more bidders and higher values of cash balances were significantly related to increased values of ϵ . For example, we obtained

$$\begin{aligned} \epsilon = & 1.77(\text{cash balances}) \\ & (38.4) \\ & + 2.71(\text{number of bidders dummy}) \\ & (5.80) \\ & - 0.0318(\text{cash balances squared}) \\ & (23.60) \end{aligned}$$

(sum of the squared residuals = 63,715.3, *N* = 1,101),

where the absolute *t* statistics are shown in parentheses. In the cases with small numbers of bidders, increased cash balances are associated with increased values of ϵ up until \$27.65, which is 2.5 times greater than the median value of cash balances of \$11.16; ϵ is also \$2.71 higher when there are at least five bidders. Since the experimenters determined both the number of bidders and ϵ , questions of causality do not seem to be important for that relationship. The problem of causality between ϵ and cash balances is more serious. One partial answer is that the level of cash balances is determined from the previous auction's bid and thus is known before ϵ is changed. However, Granger causality tests with a single lag—an admittedly imperfect solution—did not reject either hypothesis for the direction of causation. Given the possibility that ϵ was endogenous to cash balances and the number of bidders, we reran the regression specifications shown in Table 2 (though employing the entire sample) and the specification shown above in this footnote using two-stage least squares. While the variables for cash balances always had effects of the predicted sign and were significant at lower levels (smaller probability of type-I error) than those previously reported, the coefficients for the numbers of bidders variable were only significant in those regressions corresponding to specifications 1 and 5 in Table 2. For example, rerunning equations (6) and (7) resulted in

private-information bid

$$\begin{aligned} = & 0.977(\text{private signal}) \\ & (406.3) \\ & - 0.0057(\text{number of bidders}) \\ & (0.029) \\ & - 0.1167\epsilon \\ & (1.698) \\ & - 0.1490(\text{cash balances prior to bid}) \\ & (3.6484) \\ & - 5.5 \\ & (4.33) \end{aligned}$$

TABLE 4—REGRESSIONS EXPLAINING THE PROBABILITY OF WINNING AN AUCTION:
ENDOGENOUS VARIABLE IS A DUMMY VARIABLE FOR THE AUCTION'S WINNER
(ABSOLUTE *t* STATISTICS IN PARENTHESES) (*N* = 1,101)

Overall, our evidence indicates that any proof of the existence of the winner's curse and its positive variance with the number of bidders is much weaker than suggested by Kagel and Levin, whose results are sensitive to 1) accounting procedures that resulted in larger recorded losses than it was possible for individuals ever actually to realize; 2) the ending of auction series for large numbers of bidders on significantly lower profits

than for other prior auctions; 3) not controlling for the bidder's level of cash balances; and 4) the inclusion of only two of the 11 auction series. The evidence also offers additional support for our limited-liability explanation by showing that the level of cash balances affected who would win an auction.

IV. Conclusion and a Suggestion for Future Research

Two alternative explanations have been advanced for the experimental subjects' behavior in Kagel and Levin's (1986) study. Kagel and Levin argue that the behavior can only be a result of judgment errors—a failure by bidders to appreciate the fact that auctions tend to select as winners those who most overestimated item value. We have argued that the observed behavior may be a perfectly rational response to limited liability and low cash balances. The experimental data do not reject the hypothesis that bidders are responding rationally to limited liability. As to whether or not bidder's behavior still significantly differs from the norm of a rational equilibrium, resolution of that question using the current data awaits derivation of the correct norm. A possibly more feasible alternative to calculating this correct standard is to rerun the experiments in terms of a series of one-shot auctions,

($R^2 = 0.993$, sum of squared residuals = 62,650.7, $N = 1,101$) and

private-information bid
= 0.979 (private signal)
(423.0)

-0.108 (number of bidders)
(0.569)

-0.127 ϵ + 0.0012 Y
(1.927) (9.315)

-0.0773 (cash balances prior to bid)
(3.994)

-5.5
(4.33)

($R^2 = 0.994$, sum of squared residuals = 66,492.3, $N = 1,101$), where the absolute *t* statistics are shown in parentheses. The removal of the last auction in each series leaves the cash-balance variable unchanged but results in the number-of-bidders variables being negative and significant at the 0.10 level in a single-tailed *t* test.

after each of which the cash balances are reinitialized. Such an experimental setting would allow for an accurate test of the one-shot common-value auction models that are analyzed in the theoretical literature.²⁸

²⁸In their response to our criticism, Kagel and Levin cite Barry Lind and Charles R. Plott (1991). We agree that Lind and Plott's methodology of using "seller auctions" is an innovative way to control for limited-liability problems. We would like to point out, however, that Lind and Plott's results are actually consistent with our hypothesis that limited liability has exacerbated findings of the winner's curse in experimental auctions. Specifically, Lind and Plott's results show a greater winner's curse in the buyer auctions, and the RNNE predictions perform relatively better for the seller auctions. For example, in using table 2 from Lind and Plott (1991), we calculate actual average profits of -\$2.56 for the buyer auctions (the RNNE prediction is \$10.08) and actual average profits of -\$0.002 for the seller auctions (the RNNE prediction is \$0.08). (See Glenn Harrison [1989] for a discussion of the problem of not giving the participants in experiments sufficient incentive to make the correct calculations.) Thus, actual profits are 125 percent below those predicted for the buyer auctions but only 102 percent below those predicted for the seller auctions. Also, 59 percent of the buyer auctions had losses, whereas only 50 percent of the seller auctions had losses. Turning to the statistical tests in Lind and Plott, the critical *F* statistic for rejecting the RNNE restrictions at the 5-percent level is 2.64; the actual *F* statistic for the buyer auction is 30.53, while for the seller auctions it is only 5.93. Put differently, the observed significance level is much lower for the seller auctions than for the buyer auctions. From a Bayesian viewpoint, the seller auctions, which are not contained by limited liability, present weaker evidence against the RNNE prediction. This is exactly our point.

The Winner's Curse and Public Information in Common Value Auctions: Reply

By JOHN H. KAGEL AND DAN LEVIN*

In their comment, Robert Hansen and John Lott (1991 p. 360) (hereafter HL) argue that the violations of Nash-equilibrium bidding theory reported in Kagel and Levin (1986) (hereafter KL) and related publications (Kagel et al., 1989) "*may be a perfectly rational response to limited liability and low cash balances*" [emphasis added].¹ While HL's examples emphasize the importance of not overlooking the potential effects of limited liability on bidding, we controlled for this problem in two ways: 1) by choosing a design that minimizes the incentive to overbid relative to the Nash equilibrium as a result of limited-liability considerations and 2) by providing subjects with cash balances that were large enough that, for almost all bidders (48 out of 50), balances were always high enough that it *never* paid to deviate unilaterally from the Nash-equilibrium bidding strategy of a single-shot game.

The protection our experimental design affords against overbidding as a result of

limited liability is easily seen through clarification of HL's own first example. HL consider a bidder with a private-information signal of \$80 in an auction where the value of the item is \$50, the bidder has a cash balance of \$10, and $\varepsilon = \$30$ (the interval around the true value from which private-information signals were drawn). They note that any bid over \$60 would make the individual's loss greater than his cash balance, concluding that the lack of responsibility for large losses is likely to lead to higher bidding. What HL fail to point out (or do not realize) is that, in this example, the risk-neutral Nash-equilibrium (RNNE) bid is \$52.27 in a market with four bidders, or \$50.41 in a market with seven bidders, so that the bidder is fully liable for all losses (and a good deal more), relative to the Nash-equilibrium bid.² As long as bidders have sufficient cash balances to cover their maximum losses relative to their Nash-equilibrium bids, their overbidding *cannot* be rationalized in terms of a Nash equilibrium.³ Rather, overbidding must be explained on some other grounds, such as the judgmental error underlying the winner's curse.

Although HL's analysis of our data shows a statistically significant cash-balance effect, we show that the regression models HL employ are misspecified. Once their specification errors are corrected, we find 1) a statistically significant positive time trend in bidding, which is the exact opposite effect of what HL's multiperiod example predicts but

¹HL's opening statement would have the reader believe that the winner's curse is a phenomenon identified only in the laboratory but not present in "real world" markets. In fact, the term winner's curse was first introduced in the literature by petroleum geologists (E. C. Capen et al., 1971) in order to characterize what they believed to have been the outcome of bidding on outer-continental-shelf (OCS) oil-lease sales for the period 1954-1969 (also see the references cited in KL [p. 894] and Wilson's [1990] review of field data on the winner's curse).

²Here, we assume that $\bar{x} = \$25$, as HL do (see Section I for the equilibrium bid function).

³Literally, this is only a local result. However, in the simulations reported in Section I, we find that in auctions with four or seven bidders, with $\varepsilon = \$30$ and cash balances of \$4.50 (which 48 out of the 50 bidders always had), even larger deviations from the RNNE bid function are not profitable.

is consistent with our argument that multiperiod effects may promote less aggressive bidding, thereby mitigating the winner's curse, and 2) a statistically significant cash-balance effect indicating that each \$1 increase in balances reduced bids \$0.08. While the sign of the cash-balance coefficient is negative, our analytic results and simulations show that this cannot be the result of limited-liability forces. This interpretation is supported through a regression specification that eliminates all subjects who went bankrupt (including the two whose cash balances were low enough that they might have been motivated to deviate from the Nash equilibrium), with virtually no effect on the sign, the size, or the statistical significance of the cash-balance coefficient. Finally, results from another common-value auction experiment (Barry Lind and Charles Plott, 1991), which replicates our design while eliminating the limited-liability problem, reproduces our primary results, providing additional evidence that limited-liability forces do not account for the winner's-curse phenomenon reported in our experiment.

I. Limited Liability and Nash-Equilibrium Bidding in the KL Design

HL's argument that limited liability for losses may result in overbidding and other (apparent) violations of Nash-equilibrium bidding theory for perfectly rational bidders is well taken.⁴ Indeed, the central procedural issue to be resolved in designing our experiment was what to do about losses, since if bidders were not held accountable for them, it might promote bidding above the RNNE. On the other hand, if bidders were to be held liable for their losses, there was a need to specify "bankruptcy" conditions and to devise procedures to maintain a constant number of bidders. As a result, we designed an experiment that makes HL's examples (the effects on bidding when cash

balances are zero and the multiperiod effects of bidding in auctions with zero expected profit) irrelevant. Following HL, we consider single-shot auctions first and then move on to issues of limited liability in repeated auctions.

A. Single-Shot Auctions

Our experiment involved only experienced bidders who had experienced the (more) extreme effects of overbidding found among inexperienced bidders in common-value auctions (Kagel et al., 1989). Under our design, the RNNE produced positive expected profits that were increasing in x_0 , the value of the auctioned item, and in the x_i 's (individual bidders' private-information signals), which were uniformly distributed on the interval $[x_0 - \varepsilon, x_0 + \varepsilon]$. Bidders started the experiment with a cash balance of \$8 or \$10 which, they knew from experience, was theirs to keep and add to through bidding below x_0 or to lose as a result of bidding above x_0 . Further, looking at the subjects' cash balances, of the 50 bidders in our eight auction series, only two were ever bidding with cash balances below \$4.50 (for a little over half the bidders, cash balances never fell below starting levels).⁵ That is, all bidders started out being liable for losses up to \$8–\$10, and virtually all of our bidders were always liable for the first \$4.50 in losses suffered. This has important implications for the applicability of HL's limited-liability argument to our experiment.

In our design, for signals in the interval $\underline{x} + \varepsilon < x_0 < \bar{x} + \varepsilon$, the RNNE bid function is $b(x) = x - \varepsilon + Y$, where $Y = [2\varepsilon / (N + 1)] \exp[-N(2/\varepsilon)(x - (\underline{x} + \varepsilon))]$ and N stands for the number of active bidders in the market.⁶ Since Y contains a negative

⁵Most bankruptcies occurred for subjects whose cash balances stood at \$4.50 or above.

⁶HL (p. 349) argue that KL "...did not even solve for the complete equilibrium given unlimited liability." This is not correct (see footnote 8 in KL). What we do not have is an analytic solution for the differential equation specifying the equilibrium bid function for $x_i > \bar{x} - \varepsilon$, which constitutes only a small portion of the signals' domain. Further, contrary to HL's assertions

⁴We define a winner's curse as having occurred when (i) there is a high positive correlation between bids and signals and (ii) there is bidding above the expected value conditional on winning the auction.

exponential it diminishes rapidly as x_i moves beyond $\bar{x} + \varepsilon$. Further, since a bid of $\bar{x} - \varepsilon$ protects against *all* losses (x_i are drawn from the interval $[x_0 - \varepsilon, x_0 + \varepsilon]$), as long as bidders have sufficient cash balances to cover Y , they are fully liable for all losses relative to the Nash-equilibrium bid. The maximum possible value for Y is $2\varepsilon/(N+1)$ so that with $\varepsilon = \$12, \18 , and $\$30$ (the values employed in the experiment) maximum losses were $\$4.80, \7.20 , and $\$12.00$, respectively, with $N = 4$ and $\$3.00, \4.50 , and $\$7.50$, respectively, with $N = 7$.⁷ (The seeming paradox of limited liability having a greater potential impact with $N = 4$ than with $N = 7$ is explained by the fact that the RNNE bid function is decreasing in N .) Consequently, given the starting cash balances subjects had at their disposal, limited liability could only have been a factor in explaining early deviations from the RNNE in experiments with $N = 4$ and $\varepsilon = \$30$. Further, with cash balances of $\$4.50$ or more, which virtually all bidders always had, the limited-liability argument can only explain overly aggressive bidding with $N = 4$ and with $\varepsilon = \$30$ for $N = 7$. However, in our experiment (see table 3 in KL), the winner's curse was most prominent with $N = 7$ and $\varepsilon = \$12$ and $\$18$, as these treatment conditions produced negative average profits (all others produced positive average profits). This is exactly the opposite of what one would predict on the basis of HL's limited-liability argument!

Simulations help clarify the impact of limited liability in our design. In particular, they indicate that, with a cash balance of $\$4.50$, the limited-liability argument is not relevant to experiments with $N = 4$ or $N = 7$ for values of ε up to $\$30$. Table 1 reports

the results of these simulations. We consider expected profits of bidder 1 for unilateral deviations from the Nash strategy, assuming that all other bidders follow the Nash strategy. The simulation employed 25,000 draws of x_0 and corresponding random draws of x_i about x_0 , with liability for losses limited to $\$4.50$. Expected profits were calculated for player 1 at the RNNE bid and for unilateral increases in player 1's bid above the RNNE (with all other bidders playing the Nash strategy), employing increments of $\$0.50$ through the bid of $\$3.00$ and $\$1.00$ increments thereafter.

The first part of Table 1 shows the effect on player 1's expected profit with $\varepsilon = \$30$, given that $\bar{x} < x_0 < \bar{x} + \varepsilon$ and x_0 is distributed uniformly on the interval $[\bar{x}, \bar{x} + \varepsilon] = [\$30, \$230]$ (with $\bar{x} < x_0 < \bar{x} + \varepsilon$, we are sampling from the interval with the lowest expected profit, as there is zero expected profit for $\bar{x} < x_i < \bar{x} + \varepsilon$, with expected profit becoming positive and increasing monotonically for $x_i > \bar{x} + \varepsilon$). Note that unilateral deviations from the RNNE *reduce* total profit, as bidding above the RNNE lowers profit in those auctions that would have been won anyway, and these losses are larger than the increased profits earned from winning more auctions. To be sure, as HL argue, limited liability attenuates the cost of bidding above the RNNE here, as the reduction in profits for any given deviation is smaller than in the case of unlimited liability. Nevertheless, profits are reduced. Note also that expected profit is higher with $N = 7$ than with $N = 4$, as the RNNE calls for less aggressive bidding with larger N for signal values in this interval.

The second part of Table 1 shows the corresponding simulations for $\varepsilon = \$30$ and $\$115 < x_0 < \145 , the midpoint of possible x_0 values, assuming that x_0 is distributed uniformly on the interval $[\bar{x}, \bar{x} + \varepsilon] = [\$30, \$230]$. There is positive expected profit under the RNNE for all signal values in this interval. Here too, deviations from the RNNE produce uniformly lower expected profit. Further, as long as the bid deviation is $\$4.50$ or less, there is no difference between expected profit with and without unlimited liability, since in our design a bid of $x_i - \varepsilon$,

there is no difficulty in interpretation or error in our design when $x_i < \bar{x}$ or $x_i > \bar{x}$; it is just that, given the known bounds on x_0 and the symmetric distribution of signal values around x_0 , these signals are more informative about x_0 than x_i farther from the end points.

⁷Maximum potential losses occur with $x_i = \bar{x} + \varepsilon$ and $x_0 = \bar{x}$. For x_i at the midpoint of the interval of possible values used in our typical auction series ($x_i = \$125$, $\bar{x} = \$25$, $\varepsilon = \$225$), maximum losses would be $\$0.11$ for $N = 4$ and less than $\$0.005$ for $N = 7$.

TABLE 1—THE EFFECT OF UNILATERAL DEVIATIONS FROM RNNE WITH LIABILITY FOR LOSSES LIMITED TO \$4.50 AND $\epsilon = \$30$

Deviation from RNNE (dollars)	$\underline{x} \leq x_0 \leq \bar{x} + \epsilon$				$115 \leq x_0 \leq 145$			
	$N = 4$		$N = 7$		$N = 4$		$N = 7$	
	Number of auctions won	Average profit	Number of auctions won	Average profit	Number of auctions won	Average profit	Number of auctions won	Average profit

6.00	15,887	-0.7150	15,054	-0.3839	8,844	2.743	6,145	0.817

Note: Profit was averaged over all 25,000 auctions in the sample.

which closely approximates the RNNE bid function, insures against losses.

Finally, our simulations confirm the fact that, if a player has a cash balance of \$0.00, unilateral deviations from the RNNE increase expected profit, as HL's argument suggests (this happens when $\underline{x} < x_0 < \bar{x} + \epsilon$ and for values of x_0 immediately beyond $\bar{x} + \epsilon$, where Y is still significant). However, as we will show below, this does not necessarily imply that bidders with low cash balances will bid more aggressively than the RNNE model predicts.

B. Multiperiod Auctions

HL also discuss the effect of limited liability in multiperiod auctions, as it affects single-period outcomes. They note correctly that, under certain circumstances, the threat of bankruptcy from overly aggressive bidding in multiperiod auctions can completely offset the limited-liability forces that may promote bidding above the RNNE in a single-period auction. HL do not specify these circumstances but, instead, provide an example of a multiperiod auction in which limited liability in later periods induces bidders to take "unfair" gambles in early periods, even though cash balances are sufficiently large to cover all potential losses in these early periods. Unlike their single-

period-auction examples, in this example there is zero expected profit in each auction period, as there are no private-information signals, only common knowledge concerning the underlying distribution of x_0 .

In contrast, our design offers significant positive expected profits at the Nash equilibrium. Thus, bankruptcy can be quite costly in terms of precluding future positive profits. This force works *against* any single-period limited-liability forces promoting more aggressive bidding. In addition, given our experimental design, it suggests that more aggressive bidding ought to be observed as time goes on. HL have conveniently switched examples, from auctions with positive expected profit to auctions with zero expected profit, in going from their single-period to multiperiod examples, rendering their multiperiod example irrelevant to our design.

II. Reviewing the Evidence in KL

In recalculating the per-period profit from our experiment, HL note a tendency for auctions with small numbers of bidders to end with gains and for those with large numbers of bidders to end with losses; they also note that all auctions stopped with above-average gains or losses. HL conduct t tests demonstrating that these last-period

gains and losses were larger than average. They wonder how these effects could arise when the length of each auction series seems random.

The explanation is quite simple. Our experimental design called for increasing ε over time, starting with smaller ε 's, which would limit losses, to give subjects time for learning and refreshing their memories, ending with larger ε 's, for which expected profits would be larger (see table 1 in KL). In auctions with small numbers of bidders, where bids were consistently below the expected value conditional on winning, these increases in ε resulted in above-average profits for later auction periods. For auctions with large numbers of bidders, in which bids were often above the expected value conditional on winning, increases in ε would result in larger losses in these later periods. The latter did not happen on average, however, as bidders shaved their bids as ε increased (see table 3 in KL).⁸ Nevertheless, the variance of expected profit conditional on winning was increasing in ε . Further, there is an endogeneity problem in auctions with large numbers of bidders that HL fail to account for. When bidders went bankrupt, N decreased, at least to the extent that we did not have substitutes to replace the bankrupt bidders. This happened in auction series 3-large and 8-large, two of the worst offenders in HL's calculations.⁹ Bankruptcies always involved losses and usually involved relatively large losses.

HL report a series of regressions identifying cash-balance effects on bids in our private-information auctions. Most of their statistical analysis employs ordinary-least-squares techniques, which is inappropriate since, as HL themselves note, it does not account for individual-subject differences, so

that the direction of causality may run from individuals who bid too high and thus tend to have low cash balances, rather than from low cash balances to higher bids. This problem is corrected in HL's table 3, where they employ fixed-effects regression models, producing "somewhat mixed results" (p. 358) compared to their OLS regressions. These regressions are still flawed, however, as HL completely ignore the endpoint effects of signal values near \underline{x} and \bar{x} , and they fail to explore (or to report their explorations of) any multiperiod effects present in the data.¹⁰ Our regression analysis, reported in Table 2, corrects these deficiencies.

First, our regressions, unlike HL's, are restricted to signal values in the interval $\underline{x} + \varepsilon < x_i < \bar{x} - \varepsilon$, as was done in our original paper, since the form of the RNNE bid function is quite different for x_i outside this interval. Along with individual-subject dummy variables, all of our specifications include a subject $\times \varepsilon$ interaction term permitting each subject to respond differently to changes in ε , which proves to be statistically significant under all specifications (HL do not account for this interaction effect). Our preferred specification is reported as regression 1 in Table 2. It includes a time-trend variable (normalized auction period) to capture the effects of any multiperiod auction forces (HL have no time-trend variable in their regressions) and a cash-balance variable (cash balances at the time the bid was made).¹¹ The cash-balance variable is negative and statistically significant, suggest-

⁸In KL, we conjecture that this results from risk aversion.

⁹Auctions series 3-small is defined as the periods after the last bankruptcy in auction series 3. In auction series 8, one subject went bankrupt approximately 15 minutes before our two-hour time period was up, reducing the number of bidders from seven to six. Rather than proceed for one or two periods with $N=6$, the auction series was terminated.

¹⁰HL (p. 355) suggest that signal values near these endpoints were "...one other source of problems in Kagel and Levin's experimental setup." Nothing could be further from the truth (see footnote 6). Failure to account for the additional information associated with these signal values does pose statistical problems however, which HL did not account for in their table 3.

¹¹The auction-period variable is normalized to account for the different numbers of auction periods in the different auction series. Subjects were recruited for a fixed period of time, and we typically conducted as many auction periods as time permitted. Similar results are obtained using an untransformed period variable. Subject dummies are specified for each subject in each auction series; so, a subject participating in more than one auction series will have a separate dummy variable in each series.

TABLE 2—REGRESSION ANALYSES SHOWING THE IMPORTANCE OF CASH BALANCES IN EXPLAINING THE LEVEL OF BIDS: ENDOGENOUS VARIABLE IS BID, ABSOLUTE t STATISTICS IN PARENTHESES, RESTRICTED TO SIGNAL VALUES $\underline{x} + \varepsilon \leq x_i \leq \bar{x} - \varepsilon$

Public-information auctions								
Regression	Private signal	Number of bidders	Cash Balance prior to bid	Auction period (normalized) ^a	Public information	Private signal dummy (N = 6 or 7)	Public information dummy (N = 6 or 7)	F statistic for $\varepsilon \times$ subject ^b [P]
5	0.426 (8.94)	1.09 (1.11)	-0.151 (2.32)	7.20 (3.29)	0.564 (12.7)	-0.239 (4.40)	0.265 (5.13)	3.36 [0.001]

Note: In all cases, a fixed-effects regression model with individual-subject dummy variables was used.

^aNormalized auction-period variable is $[1/\text{last auction period}] \times [\text{auction period}]$.

^bCoefficient estimates for ε are not unique given the $\varepsilon \times$ subject dummy variables. There was a statistically significant main effect due to ε in all cases.

^cExcludes subjects who went bankrupt.

ing that each \$1 increase in cash balances produces an \$0.08 decrease in bids. The auction-period variable is positive and statistically significant, indicating that what multiperiod effects are present in the data tend to mitigate the winner's-curse effect in early auction periods, as we would expect in a design with positive expected profits.¹²

Specification 2 drops the auction-period variable. Under this specification the cash-balance variable, while still negative, is sharply reduced in size and fails to achieve statistical significance at conventional levels. This, in conjunction with specification 1,

suggests that, as the threat of being excluded on account of bankruptcy from potentially profitable auctions grew smaller, subjects bid more, but this effect was weaker for bidders with larger cash balances (average cash balances were relatively flat or decreased moderately over the initial auction periods and were increasing over later auction periods, as the survivors generally earned positive profits and bankrupt bidders were eliminated from the auction once their cash balances turned negative).

Specification 3 repeats the first specification but excludes those bidders who went bankrupt. There is virtually no difference in parameter estimates from the first specification. In excluding subjects who went bankrupt, we excluded the two subjects whose cash balances dropped below the \$4.50 threshold employed in our simulations. The fact that the coefficient for the cash-balance variable remains virtually unchanged, in conjunction with our simulation

¹²Given the varied and often puzzling regression specifications reported in HL, in conjunction with their multiperiod limited-liability argument, it is hard to believe that they did not attempt a specification including a time-trend variable. The fact that our results completely contradict their multiperiod example suggests why such a specification is not reported (Edward Leamer, 1983).

results, provides conclusive evidence that the negative coefficient associated with this variable is not a result of limited-liability forces.¹³

Specification 4 includes the cash-balance \times private-signal interaction term that HL are so fond of in their regressions. A cash-balance \times signal interaction term with the sign they report (which is negative; see specification 6 in table 3 in HL) is puzzling given their limited-liability argument, since it implies that a low cash balance will promote higher bidding with higher signal values and lower bidding with lower signal values, whereas, if anything, we would anticipate the opposite pattern in response to any limited-liability forces.¹⁴ The estimated size of the coefficient value is trivial (-0.00011) and has a t statistic of 0.33 in our specification, hardly suggestive of a robust force underlying auction behavior.

We also checked for multiperiod effects and cash-balance effects in auctions with public and private information. After all, these are also common-value auctions with the possibility for losses, so that HL's limited-liability argument should apply here as well. Regression 5 reports our preferred specification, which matches the underlying specification of the first regression in table 8 of KL, with the addition of an auction-period variable and a cash-balance variable. Here too, we observe a positive, statistically significant, time-trend coefficient and a negative, statistically significant, cash-balance coefficient, results that are qualitatively similar to but quantitatively stronger than those reported with private information only. Note

that, although there was considerable variability in profits in these auctions, on average they were only slightly lower than the RNNE prediction (KL, p. 911). Hence, the negative coefficient associated with the cash-balance variable here cannot be attributed to limited-liability forces either.

While the regression results in Table 2 are interesting, we caution the reader against placing undue reliance on them as there is some question regarding the stability of the coefficients across auction series. This manifests itself in the fact that we observe a statistically significant cash-balance \times auction-series interaction effect in the auctions with public and private information and a statistically significant auction-period \times auction-series interaction effect in both data sets. There is considerable variability among auction series in these coefficients, so the results in Table 2 reflect average tendencies for the experiment as a whole.¹⁵ There is a need to explore these multiperiod and cash-balance effects experimentally.

III. Additional Evidence

For an experimenter, the ultimate resolution of the limited-liability issue can only be obtained through additional experiments aimed at assessing the effects of exogenous variation in cash balances on bidding. Fortunately, there already exist some data relevant to the issues raised. First, in a series of common-value offer auctions in which the starting cash balance for two student groups was set at \$10, with the starting balance for the third group set at \$20, simple compar-

¹³We also looked at the data for the two subjects who were bidding with cash balances below \$4.50. Neither of them lasted very long, but both had very low balances: \$0.52 and \$0.23. Both bidders discounted their bids, relative to their signal values, *more* with these low cash balances than when they were bidding with the original balance of \$10.00.

¹⁴With higher signal values, expected profits conditional on winning the auction are increasing, at least up to the point at which the Y term is close to zero. It is only the possibility of negative profits at the Nash equilibrium that gives rise to a potential limited-liability problem in our design.

¹⁵Additional empirical analysis of the effects of cash balances on bidding is reported in Kagel et al. (1989), in this case for inexperienced bidders, for whom the likelihood of low cash balances and bankruptcy was substantially higher than for the experienced bidders studied here. The regressions reported in Kagel et al. (1989) show that higher cash balances generally promoted higher bidding, although we cannot distinguish whether this is a cash-balance effect or a possible learning effect, as subjects may have had to suffer real losses in order to learn to bid less.

isons of mean differences in profits between groups (controlling for ε) showed no significant differences between auction series (Douglas Dyer et al., 1989).

Second, Lind and Plott (1991) report results from a common-value auction experiment with two alternative procedural modifications designed to control for any limited-liability effect. Under one procedure, the common-value auction experiment in which bidders might lose money was conducted simultaneously with a second experiment in which subjects were making money. The second procedure involved sellers in a common-value auction in which the seller's loss occurs as an opportunity cost, so the possibility of bankruptcy does not exist. Lind and Plott find a winner's curse in both settings.

IV. Summary and Conclusions

We agree with HL's argument that limited liability for losses may result in overbidding and other (apparent) violations of Nash-equilibrium bidding theory on the part of perfectly rational bidders. However, our analysis and the results of Lind and Plott (1991) show that this argument is not relevant to our experimental design.

We are not surprised to find an HL type of comment. It is not the first time that some economists have employed acrobatics to avoid facing a phenomenon that does not agree with their prior beliefs. Both this reply and the work of Lind and Plott clarify the fact that financially motivated individuals can and do make judgmental errors in a

market setting, and the winner's curse is alive and well, and not the result of limited-liability effects as HL speculate.

Some Evidence on the Winner's Curse: Comment

By DAN LEVIN AND JAMES L. SMITH*

The theory of auctions has developed extensively since Robert B. Wilson's (1977) seminal paper. Due to the complexity of equilibrium strategies, however, empirical researchers have been slow to incorporate and test the most basic theoretical precepts.¹ Typical empirical studies estimate ad hoc bidding models, with no attempt to ascertain whether the implied behaviors are theoretically plausible.

The recent paper by Stuart E. Thiel (1988) attempts to bridge this gap. Thiel obtains closed-form equilibrium bidding functions that are theoretically motivated and linear in parameters, and which facilitate empirical estimation and testing. If widely applicable, Thiel's empirical approach would constitute a major methodological breakthrough.

Unfortunately, Thiel's approach applies only in special cases that are of limited practical interest. Linear bidding strategies emerge only under circumstances that are unlikely in the real world. The limited range of Thiel's approach may not be apparent to casual readers of his paper.

Even when linear strategies do exist, they are not unique under the special assumptions of Thiel's model. For each Nash equilibrium in linear strategies, there exists a

related family of nonlinear strategies. Thus, further justification must be found for basing empirical research on the linear specification.

We also note a significant error in Thiel's work. The symmetric strategies he derives on the basis of order statistics do not constitute a Nash equilibrium. We derive proper expressions for the symmetric Nash strategies and discuss a specification error in Thiel's regression analysis that would account for the mixed results obtained in his application to the highway-construction industry.

I. Linear Nash Strategies

Like Thiel, we consider a common-value auction in which each bidder observes a random signal X_i , with variance σ^2 , which is an estimate of the unknown value θ of the item being auctioned. $F(X_i|\theta)$ represents the conditional distribution of the i th bidder's estimate, and $\phi(\theta|X_i)$ represents the bidder's posterior density for θ given the signal X_i . Let $B(X)$ represent the symmetric equilibrium strategy used by each of n bidders, with $B'(\cdot) > 0$ such that the inverse $r(B) = B^{-1}$ is defined. If all other bidders are using this strategy, then the i th bidder's problem may be written as

$$\max_{B(X)} \int_{\Sigma \theta|X} (\theta - B) F(r(B)|\theta)^{n-1} \phi(\theta|X) d\theta$$

with first-order condition given by

$$0 = \int_{\Sigma \theta|X} [(\theta - B)(n-1)F(r(B)|\theta)^{n-2} \\ \times f(r(B)|\theta)r'(B) \\ - F(r(B)|\theta)^{n-1}] \phi(\theta|X) d\theta.$$

The authors thank John Kagel for initially calling their attention to the issues raised in this paper and for providing some of the motivation to work them out. The authors also thank an anonymous referee who provided helpful comments on an earlier draft. The research leading to this paper was supported by the University of Houston Energy Laboratory. Dan Levin also acknowledges support from the Sloan Foundation and the National Science Foundation. These parties are not responsible for the contents of the current paper.

¹Richard Engelbrecht-Wiggans and Robert J. Weber (1979) have shown that symmetric equilibrium strategies do not even exist in closed form, except in simplified common-value auction settings.

At the symmetric equilibrium, $r(B) = X$ and $r'(B) = B'(X)^{-1}$. Thus,

$$(1) \quad B'(X)$$

$$= \frac{\int_{\Sigma \theta | X} (\theta - B)(n-1)F(X|\theta)^{n-2}f(X|\theta)\phi(\theta|X) d\theta}{\int_{\Sigma \theta | X} F(X|\theta)^{n-1}\phi(\theta|X) d\theta}.$$

A symmetric equilibrium must satisfy this differential equation and possibly other boundary conditions dictated by the context of the bidding problem.²

Thiel implicitly imposes the following three restrictions which guarantee the existence of linear strategies.

- 1) Each bidder's prior distribution of value is diffuse: $\phi(\theta)$ is constant for all θ .
- 2) Estimation errors are statistically independent of the item's true value: $F'(X_i - \theta|\theta) = f(X_i - \theta|\theta) = f(X_i - \theta)$.
- 3) Each bidder's estimate of the value is unbiased: $E(X_i) = \theta$.

Under restrictions 1–3, equation (1) reduces to

$$(2) \quad B'(X) + K_1 B(X) + K_2 - K_1 X = 0$$

where

$$K_1 = \frac{n(n-1)}{\sigma} \int_{\Sigma z} F(z)^{n-2} f(z)^2 dz > 0$$

$$K_2 = n(n-1) \int_{\Sigma z} z F(z)^{n-2} f(z)^2 dz$$

$$z = \frac{(X - \theta)}{\sigma}$$

(see Appendix). The general solution to

equation (2) is

$$(3) \quad B(X) = X - \frac{(1 + K_2)}{K_1} + \beta \exp(-K_1 X)$$

(see Appendix). However, additional conditions must be imposed to ensure individual rationality of the proposed solution. In the present case, these conditions imply $\beta \leq 0$ (see Appendix). Only in the special case of $\beta = 0$ is the bidding function linear.

Linear strategies are not unknown in the literature. Previous researchers have noted their existence under the restrictions of Thiel's model. Richard Engelbrecht-Wiggans and Robert J. Weber (1979) were among the first to discuss the necessity of a diffuse prior (restriction 1). Michael H. Rothkopf (1980) and Robert L. Winkler and Daniel G. Brooks (1980) provided examples in which independent estimation errors (restriction 2) were used to derive linear bidding functions. More recently Wilson (1988) showed that bidding strategies converge to linearity as normally distributed priors become diffuse in the limit.

The main problem is that the necessary conditions for linear strategies rule out most cases that are of any empirical interest. For example, the restriction to a diffuse prior eliminates auctions with bounds on the value of the item being sold. Zero is often a relevant bound—one that imposes structure on bidder's priors. The announcement of presale value estimates or reservation prices by the seller is another real-world phenomenon that undermines diffuse priors and linear strategies. In practice, it is hard to think of auctions in which prior information would not limit Thiel's approach, even in the highway-construction market to which his method is applied.

II. Examples

Our derivation of equilibrium strategies highlights two further problems with Thiel's (1988) paper. First, the solution in linear strategies is not a unique equilibrium. Equation (3) admits a continuous family of

²Typically, initial conditions stemming from the boundedness of value estimates identify a unique bidding function, as in Douglas K. Reece (1978) and Robert B. Wilson (1988). When value estimates are unbounded, as in Thiel's model, the standard conditions do not apply.

nonlinear strategies as well. Whether bidders would select the linear strategy is uncertain.³ Second, the bidding function Thiel derives by manipulating order statistics is not a Nash equilibrium. We present two examples that illustrate these points.

A. The Uniform Distribution

Let value estimates follow an unbiased uniform distribution over the interval $[\theta - \varepsilon, \theta + \varepsilon]$. As shown in the Appendix, any function of the following form constitutes a symmetric equilibrium:

$$B(X) = X - \varepsilon + \beta \exp[-nX/2\varepsilon]$$

for any $\beta \leq 0$.

The linear form, $B(X) = X - \varepsilon$, is obtained as a special case by choosing $\beta = 0$.

Thiel's bidding function in the uniform model reduces to

$$B(X) = X - \varepsilon(n^2 - n + 2)/(n^2 - 1)$$

which corresponds to the equilibrium only when $n = 3$.

B. The Normal Distribution

Let value estimates follow an unbiased normal distribution with mean θ and variance σ^2 . Then, the transformed value estimates $(X - \theta)/\sigma$ follow the standardized normal distribution function, $G(0,1)$. As shown in the Appendix, any function of the following form constitutes a symmetric equilibrium:

$$(4) \quad B(X) = X - \alpha_n \sigma + \beta \exp[-\xi_{n:n} X / \sigma]$$

for any $\beta \leq 0$

³Refinement of the Nash equilibrium concept will not eliminate the nonlinear strategies, since all Nash equilibria here are strict equilibria. This implies that each of the multiple equilibria is perfect in the sense of Reinhard Selten (1975). See Selten (1975) for the discrete case and Ronald M. Harstad and Levin (1986) for the continuous case.

where

$$\alpha_n = \frac{\int_{-\infty}^{+\infty} t^2 dG(t)^n}{\int_{-\infty}^{+\infty} t dG(t)^n}$$

$$= \frac{\int_{-\infty}^{+\infty} t^2 dG(t)^n}{\xi_{n:n}}$$

and where $\xi_{n:n}$ is Thiel's (1988) symbol for the expected value of the highest (standardized) value estimate received by any bidder. The linear form of equation (4), obtained by choosing $\beta = 0$, corresponds exactly to the bidding function Wilson (1988) obtains when his prior is made diffuse in the limit, and it agrees with Winkler and Brooks's (1980) result for the special case $n = 2$. For comparison with Thiel (1988), the linear version of our equation (4) can be rewritten as

$$(5) \quad B(X) = X - \sigma(1 + K_2)/\xi_{n:n}.$$

Thiel's bidding function, evaluated in the normal case, again departs from equilibrium:

$$B(X) = X - \sigma \left[\xi_{n:n} + \frac{(\pi/2)^{1/2}}{(n-1)} \right].$$

What is awry? Thiel does not properly formulate the relationship between the bidder's estimate and the probability of winning. The bidder's estimate affects his probability of winning in two ways: first, through its impact on the perceived distribution of competing bids, and second, through its impact on the level of his own bid. Thiel's differentiation of his equation 2 ignores the first effect.

III. A Warning to Empiricists

We have argued that the assumptions underlying Thiel's (1988) model are seldom satisfied in the real world. Is it possible nevertheless that linear bidding functions provide approximations that are good

enough for empirical work? The evidence is not encouraging.

Some evidence is found in Thiel's own study of the highway-construction industry. He noted the "wholesale breakdown" of the linear model in cases where the value of the contract is estimated by the state and divulged prior to bidding (p. 886). In cases where presale estimates were not divulged, Thiel's linear model seemed to fit better. What could account for this pattern? Divulging the state's estimate imposes structure on the bidders' prior distributions. If priors are not diffuse, Thiel's linear specification is not admissible (i.e., there is a specification error in the functional form of Thiel's regression equation). The cases in which presale estimates were not divulged to potential bidders do not so obviously violate Thiel's maintained hypothesis of diffuse priors. In these cases, Thiel's linear functional form is at least admissible, although the constant term in the regression equation would be misspecified, due to his mathematical error. In summary, suspected violations of Thiel's stringent paradigm tend to explain the pattern of his empirical results.⁴

If linear bidding functions are used for convenience in empirical work, how far out of equilibrium are they likely to be? This depends upon the context, so no general answer is possible. However, some illustrative results are available. In simulation studies of auctions styled after the market for offshore petroleum leases, Engelbrecht-Wiggans (1979, 1983) found that any bidder could increase expected profits up to 40 percent by departing unilaterally from an equilibrium based on second-best linear strategies and submitting optimal (nonlinear) bids instead. Bidders have strong incentives not to use linear strategies except under extremely unlikely circumstances. They have no incentive to use Thiel's linear strategies under any circumstances.

⁴Engelbrecht-Wiggans and Weber (1979) warn specifically against linearity in cases where presale value estimates are divulged by the seller.

APPENDIX

Consider a common-value auction in which each of n bidders observes a random estimate X_i of the unknown value θ of the item being auctioned. Let $F(X_i|\theta)$ represent the conditional distribution function of the i th bidder's estimate and let $f(X_i|\theta)$ represent the density. Each bidder's posterior density for θ can be written as $\phi(\theta|X_i) = f(X_i|\theta)\phi(\theta)/f(X_i)$, where $\phi(\theta)$ represents the bidder's prior distribution of values and $f(X_i)$ represents the marginal distribution of signal X_i . We let $B(X)$ represent the symmetric equilibrium strategy used by each bidder, with $B'(\cdot) > 0$, such that the inverse $r(B) = B^{-1}$ is well defined.

As shown in the text, the necessary condition for the i th bidder can be written as

$$(A1) \quad B'(X) = \frac{\int_{\Sigma \theta|X} (\theta - B)(n-1)F(X|\theta)^{n-2}f(X|\theta)\phi(\theta|X) d\theta}{\int_{\Sigma \theta|X} F(X|\theta)^{n-1}\phi(\theta|X) d\theta}$$

While this expression is not tractable for the general case, it can be evaluated under restrictions 1–3, which characterize Thiel's model. Restriction 1 (diffuse prior) implies that $\phi(\theta) = k$, a constant for all θ . Restrictions 2 and 3 (unbiased and independent errors) affect the form of $f(X_i|\theta)$. After applying restriction 1 to equation (A1) and simplifying, we have

$$(A2) \quad B'(X) = \frac{\int_{\Sigma \theta|X} (\theta - B)(n-1)F(X|\theta)^{n-2}f(X|\theta)^2 d\theta}{\int_{\Sigma \theta|X} F(X|\theta)^{n-1}f(X|\theta) d\theta}$$

For future reference, we note that

$$\begin{aligned} F(X|\theta) &= \int_{-\infty}^X f(\tau|\theta) d\tau = \int_{-\infty}^{X-\theta} f(t|\theta) dt \\ &= \int_{-\infty}^{X-\theta} f(t) dt = F(X-\theta) \end{aligned}$$

where $t = \tau - \theta$. The third equality is due to restriction 2, while the last equality is by definition. We can now rewrite equation (A2) as

$$(A3) \quad B'(X) = \frac{\int_{\Sigma \theta|X} [(X-B) + (\theta-X)](n-1)F(X-\theta)^{n-2}[\sigma f(X|\theta)]^2 \sigma^{-2} d\theta}{\int_{\Sigma \theta|X} F(X-\theta)^{n-1}[\sigma f(X|\theta)] \sigma^{-1} d\theta}$$

Let $z = (X - \theta)/\sigma$ and $dX/dz = \sigma$. Then, $f(z) = \sigma f(X|\theta)$ and $d\theta = -\sigma dz$. Applying these transforma-

tions to equation (A3) yields

$$(A4) \quad B'(X) = \frac{\int_{\Sigma_z} \left(\frac{X-B}{\sigma} - z \right) (n-1) F(z)^{n-2} f(z)^2 dz}{\int_{\Sigma_z} F(z)^{n-1} f(z) dz}.$$

The denominator is simply $1/n$, so equation (A4) can be rewritten as

$$(A5) \quad B'(X) + K_1 B(X) + K_2 - K_1 X = 0$$

where

$$K_1 = \frac{n(n-1)}{\sigma} \int_{\Sigma_z} F(z)^{n-2} f(z)^2 dz > 0$$

$$K_2 = n(n-1) \int_{\Sigma_z} z F(z)^{n-2} f(z)^2 dz.$$

$B(X) = X - (1 + K_2)/K_1$ solves equation (A5). A general solution to the homogeneous part of (A5) is $B(X) = \beta \exp(-K_1 X)$. Thus, the general solution to equation (A1) is

$$(A6) \quad B(X) = X - (1 + K_2)/K_1 + \beta \exp(-K_1 X).$$

Individual rationality restricts β to be nonpositive. To see why, assume the contrary, $\beta > 0$. Then, if $1 + K_2 > 0$, for any $X < -(1/K_1) \ln[(1 + K_2)(\beta K_1)]$, we would have $B(X) > X$, which assures negative expected profits for that X . If $1 + K_2 \leq 0$, then, for any X , we again have $B(X) > X$ and negative expected profits. This result draws on the fact that the estimate X is unbounded in Thiel's (1988) model, since he assumes unbounded θ and independent errors. We therefore conclude that $\beta \leq 0$.

We now characterize the complete family of Nash equilibria that arise in two special cases often treated in the literature.

A. Uniformly Distributed Errors

We assume that X_i is distributed uniformly over the interval $[\theta - \varepsilon, \theta + \varepsilon]$. In this case, equation (A1) reduces to

$$(A7) \quad B'(X) = \frac{\int_{X-\varepsilon}^{X+\varepsilon} (\theta - B)(n-1)(X + \varepsilon - \theta)^{n-2} d\theta}{\int_{X-\varepsilon}^{X+\varepsilon} (X + \varepsilon - \theta)^{n-1} d\theta}.$$

Integrating the numerator by parts and rearranging, we obtain

$$(A8) \quad B'(X) + \frac{nB(X)}{2\varepsilon} - \left[\frac{n(X - \varepsilon)}{2\varepsilon} + 1 \right] = 0.$$

The general solution to this first-order, linear differential equation is given by

$$(A9) \quad B(X) = X - \varepsilon + \beta \exp[-nX/2\varepsilon].$$

The individual rationality condition ($\beta \leq 0$) in this case assures $B(X) \leq X - \varepsilon$ and guarantees positive profits for the winner, since θ cannot be more than ε away from the observed X .

Evaluating Thiel's (1988) equation 3 when X_i is assumed to follow a uniform distribution over the interval $[\theta - \varepsilon, \theta + \varepsilon]$ produces the linear function

$$(A10) \quad B(X) = X - \varepsilon[(n^2 - n + 2)/(n^2 - 1)]$$

which violates our necessary condition for equilibrium.

B. Normally Distributed Errors

We assume that X_i is distributed normally with mean θ and variance σ^2 . Integrating the expressions for K_1 and K_2 by parts then gives

$$K_1 = \sigma^{-1} \int_{-\infty}^{+\infty} t dG(t)^n$$

$$1 + K_2 = \int_{-\infty}^{+\infty} t^2 dG(t)^n.$$

Thus, equation (A6) becomes

$$(A11) \quad B(X) = X - \alpha_n \sigma + \beta \exp[-\xi_{n:n} X / \sigma]$$

where

$$\alpha_n = \frac{\int_{-\infty}^{+\infty} t^2 dG(t)^n}{\int_{-\infty}^{+\infty} t dG(t)^n}$$

$$= \frac{\int_{-\infty}^{+\infty} t^2 dG(t)^n}{\xi_{n:n}}$$

and where $\xi_{n:n} = \sigma K_1$ represents the expected value of the highest (standardized) value estimate received by any bidder.

As argued for the general case, we cannot have $\beta > 0$. On the other hand, $\beta \leq 0$ implies $B(X) \leq X - \alpha_n \sigma < X - K_1 \sigma = X - \xi_{n:n}$. (The strict inequality is based on $\alpha_n = (1 + K_2)/K_1$, which by Schwarz's inequality must exceed K_1). Since the right-most term in the string of inequalities represents the expected value of θ given that X is the highest estimate, the condition $\beta \leq 0$ assures positive expected profits.

For comparison with Thiel (1988), assume $\beta = 0$ and rewrite equation (A11) as

$$(A12) \quad B(X) = X - \sigma(1 + K_2)/\xi_{n:n}.$$

Evaluating Thiel's function when X_i is assumed to follow a normal distribution gives

$$(A13) \quad B(X) = X - \sigma \left[\xi_{n:n} + \frac{(\pi/2)^{1/2}}{n-1} \right].$$

Ski-Lift Pricing with Applications to Labor and Other Markets: Comment

By TYLER COWEN AND AMIHAI GLAZER*

In a recent article for this *Review*, Robert Barro and Paul Romer (1987) argue that nominal price stickiness can be compatible with the optimal provision and utilization of excludable goods. The paradigmatic case examined by Barro and Romer is the ski lift: instead of charging for each ride, a comparable equilibrium can be attained by charging a single price for access to the ski lift and using a quantity constraint to limit an individual's number of rides.

In particular, the more people show up to ski, the fewer rides each person can get, so that the real price of a single run down the slope increases. Crowding costs thus serve as a substitute for the flexibility of nominal prices by automatically changing the real prices individuals face.

Although Barro and Romer develop some imaginative applications of their analysis, they do not indicate that the basic model is a rediscovery of the theory of clubs (James Buchanan, 1965; Richard Cornes and Todd Sandler, 1986; Suzanne Scotchmer, 1985). In fact, Scotchmer (1985) explicitly mentions ski lifts as an example of clubs. Barro and Romer cite Frank Knight (1924), whose article was a forerunner of the theory of clubs, but do not mention that many of their primary results are well known in the public-economics literature.

The theory of clubs is concerned with the optimal size of a congestible facility, the

optimal intensity of its use, and pricing methods that lead to profit maximization and to social optimality. These questions correspond to the issues in Barro and Romer which involve the optimal number of skiers and the optimal price for a ski-lift ticket. Membership fees for clubs are analogous to ticket prices for the ski lift. The number of rides that skiers obtain is analogous to congestion in club theory; congestion reduces each user's utility as the number of people who visit the facility increases.

In an undergraduate text, Robin Boadway and David Wildasin (1984 p. 97) note that the optimal number of users of a club is reached when the per-person price equals the marginal congestion cost imposed by a single club member. In the context of the ski-lift example, the price of a lift ticket must equal the value of the rides that other skiers are deprived of. Romer and Barro (1987 pp. 878-9, 886) obtain an analogous result.

Many of the conclusions Barro and Romer obtain by making stringent assumptions about the effect of increased congestion (each skier obtains proportionally fewer rides) are derived by the theory of clubs from more general assumptions about the effect of congestion. Boadway and Wildasin (1984 p. 98) present the following summary of the results of club theory for the case in which intensity of use is fixed:

If exclusion is possible without cost and if the costs of providing the good are constant, the competitive market mechanism can be relied upon to provide an economy of many individuals with the correct size of facility and the correct number of members, and, therefore, the correct number of such facilities for the entire population.

*Cowen: Department of Economics, George Mason University; Glazer: Department of Economics, University of California, Irvine, CA 92717. We thank Suzanne Scotchmer, Esko Niskanen, and an anonymous referee for their comments, and members of the Transportation Economics Study Group at U.C. Irvine for stimulating discussions.

Similar conclusions are reached under yet more general assumptions by Scotchmer (1985).

Other results in Barro and Romer correspond to results in club theory: markets attain the optimum even if different ski areas vary in quality, that is, even if clubs congest at different rates. Also, the competitive solution is socially optimal when consumers have heterogeneous preferences if separate ski-lift areas serve consumers with different preferences (see Cornes and Sandler, 1986 Ch. 11).

Though there is no novelty in the problems Barro and Romer treat and no novelty in the conclusion that competitive markets can efficiently provide congestible goods, Barro and Romer do extend the theory of clubs in two important directions. First, they show that, under some conditions, efficiency can be attained by an entry fee alone; the effect of increased congestion on demand can obviate the need for imposing a price on each ride. (In contrast, Eitan Berglas [1976] and Scotchmer [1985, 1987] demonstrate that, in general, efficiency requires imposing a price for each ride.) Second, Barro and Romer offer the interesting possibility that, in some cases, both profit-maximization and efficiency imply constant prices following changes in demand.

Ski-Lift Pricing, with Applications to Labor and Other Markets: Reply

By ROBERT J. BARRO AND PAUL M. ROMER*

After we wrote our paper on pricing at ski areas (Barro and Romer, 1987), we received several comments like that of Tyler Cowen and Amihai Glazer (1991), noting that our results could be interpreted as special cases of results that have been established in club theory. We also received comments claiming that our results were clearly wrong because they contradicted standard results in club theory. (We now sympathize with the economist who was reportedly told by a critic that "your result is trivial, wrong, and I already proved it.")

When we wrote our paper, we were aware that ski areas were sometimes mentioned as examples of club goods (see, for example, the paper by Suzanne Scotchmer [1985]). We did not pursue the literature on clubs because our problem contained no club goods. The goods we dealt with, rides up a chair lift, are conventional private goods. Our result also contradicted the one result from club theory that we knew. The standard club analysis of a ski area treats it as a shared facility. Each member in the club decides how intensively to use this facility. In this setting, Eitan Berglas (1976) first showed that both a membership fee and a usage fee are necessary to support an efficient allocation. Our finding was that queues with no usage fee support an efficient allocation.

Nevertheless, Cowen and Glazer are correct that our results have much in common with results from club theory. Specifically, our results can be interpreted as special cases of results for clubs that are not subject to variable intensity of usage. There are

therefore two interesting questions: why does the analysis of a problem with private goods resemble the analysis of a problem with club goods? and why does our problem resemble a club problem in which people cannot vary how often they use the shared facilities?

The answer to both of these questions depends on the observation that it is possible to treat a bundle of private goods as a club good. Under the usual definition, both club goods and private goods are excludable. What distinguishes a club good is the assumption that it is partially nonrival. Because it is less than fully rival, many people can use a club good at the same time. Because the nonrivalry is only partial, increased usage by one person reduces the benefits of the good enjoyed by the other consumers. This reduction in benefits is typically labeled congestion.

To see that any bundle of private goods can be treated as a club good, consider a crop of apples. Individual apples are private goods, but the crop can be viewed as a good that many people consume. If one person eats an additional apple, total consumption of apples by others goes down. The loss of apple services that this person imposes on others can be treated as a congestion cost, but it is a special kind of congestion.

In the usual analysis of club goods, each individual chooses the intensity of usage taking the total intensity of usage by others as given. With some club goods, independent choices of the intensity of usage are feasible. Total capacity (for example, the size of a swimming pool) does not limit the total level of usage (the total number of person-hours spent in the pool). However, for club goods that are bundles of private goods, it does not make sense to assume that each individual can decide how much to use the club good, holding constant the

*Department of Economics, Harvard University, Cambridge, MA 02138 and Department of Economics, University of California, Berkeley, CA 94720.

usage by others. The total number of ski runs cannot exceed the total number of lift rides; the total number of apples consumed cannot exceed the supply of apples.

In most models of private goods, the supply of goods is allocated among the demanders by a price mechanism. We noted that when demanders are the same, any symmetric allocation device, including a queue, can serve this purpose. In either case (club goods or private goods), the notion of an independent decision concerning the intensity of use or amount of consumption does not make sense. In our problem, individual skiers seem to be able to choose freely how many runs to take, but in fact, each of them is constrained by the fixed supply of runs.

The point made by Cowen and Glazer can therefore be rephrased as follows: an equilibrium in which bundles of private goods are allocated by an entry fee, a zero per-unit fee, and quantity constraints is isomorphic to an equilibrium for club goods in which there is no intensity decision. This formal connection is useful, but it is important to recognize that there is something special about the implied form of congestion. Recognizing that the underlying goods are bundles of private goods, rather than true club goods, is crucial to the demonstration that queues can have negligible efficiency costs. Because the goods are private, the associated congestion costs take on the same form imposed by the person who eats an extra apple. This congestion reflects the fact that supply is fixed. There cannot be too much congestion.

We started with bundles of private goods and have now learned that they can be treated as club goods. There is a complementary analysis that starts with a general description of club goods and shows that these goods can sometimes behave like private goods. Consider a situation in which there is no decision about the intensity of use. Let the club benefits received by any member be written in the form $f(x, n)$, where x is a measure of capacity and n is the total number of users. Berglas and David Pines (1981) show that if $f(\cdot)$ is homogeneous of degree zero in x and n , then the

analysis reduces to the case of goods that are essentially private. This would be the case that applies to the apple harvest. If there are twice as many apples and twice as many identical apple-eaters, benefits received by any person remain the same.

In the third section of our paper, we reconsidered the two-roads problem suggested by Pigou and showed that, under certain functional-form assumptions, spots on the road for cars seemed to be like private goods. In the textbook analysis, free access to two different roads leads to wasteful congestion, because users will equate the average benefits on the two roads: $f(x_1, n_1) = f(x_2, n_2)$. The condition for optimality is that the marginal effect on benefits should be equated: $(d/dn_1)[n_1 f(x_1, n_1)] = (d/dn_2)[n_2 f(x_2, n_2)]$. In our analysis, we noted that the first equality implies the second if $f(x, n)$ is homogeneous of degree zero. This is precisely the point made by Berglas and Pines. If $f(\cdot)$ is homogeneous of degree zero, the problem is really one of private goods, not club goods.

In our paper, we also noted that the first equality implies the second if $f(\cdot)$ takes the more general form $f(x, n) = xn^{-\alpha}$ for any α . In private communication, David Pines observed that, subject to a nonlinear change $\sigma(\cdot)$ in the units used to measure the scale of capacity x , this more general form could be interpreted as a special case of the previous homogeneity result. The general assumption on f that causes the first equality to be equivalent to the second is that the function takes the form $f(x, n) = g(\sigma(x)/n)$. Our special case follows when $g(z) = z^{-\alpha}$ and $\sigma(x) = x^\alpha$.

While it is formally possible to treat a bundle of private goods as a club good, it may sometimes obscure, rather than clarify, the analysis. For example, in their textbook, Richard Cornes and Todd Sandler (1986 p. 190) describe a golf course at a country club as a club good that should carry a usage fee. They observe that usage fees are almost never charged and conclude that large transactions costs must be present. This assertion seems as implausible to us as the assertion that it is prohibitively expensive to charge for lift rides by the ride.

The usual club-theory prediction that zero usage fees will lead to wasteful congestion would be right if an unlimited number of golfers could freely enter a course and start hitting golf balls, but this is not how golf courses operate. The opportunity to start a round of golf at a specific time is just like the chance to ride on a particular chair on a chair-lift. It is a rival good. The same kind of analysis as for the ski area suggests that unobserved transactions costs need not be present and that the hypothesized welfare losses from mispricing and congestion may be negligible. No efficiency losses will be present if the members of the country club have similar tastes and the club imposes quantity constraints in a way that does not waste resources, for example: by a reservation system that is random and does not reward effort. A typical such reservation system, widely used in private clubs and university athletic organizations, lets individuals make a single reservation by phone, one day in advance, and only after a certain time (e.g., 8:00 A.M.).

A Model of Housing Tenure Choice: Comment

By YUMING FU*

In their paper in this *Review*, Vernon Henderson and Yannis Ioannides (1983) employed a two-period housing-consumption-investment model to study tenure-choice behavior. One of their major findings is that the demand for housing investment is independent of wealth, given the income path, but increases as income tilts forward. Since the demand for housing consumption increases with wealth, wealthier people are more likely to rent the housing they consume, given the income path. The purpose of this note is to show that their comparative-statics result for housing investment demand (equation 17a) contains an incorrect sign.¹ The correct result indicates that the demand for housing investment responds positively to the change in wealth, rather than to the change in the income path. As a result, whether or not wealthier people are more likely to rent the housing they consume depends on the relative magnitudes of the income elasticities of housing consumption versus investment demand. Also, Henderson and Ioannides' comparative-statics result for the savings demand (equation 17c) is incorrect. Since the demand for housing consumption, for housing investment, and for savings cannot be separated, this note corrects that error as well. The results presented in this note should make the intuition underlying Henderson and Ioannides' tenure-choice model clearer.

I. The Correct Comparative Statics and the Interpretation

Adopting the notation of Henderson and Ioannides (1983) and following their formu-

*Faculty of Commerce and Business Administration, University of British Columbia, 2053 Main Mall, Vancouver, BC, Canada V6T 1Y8. I thank Lawrence D. Jones and Robert W. Helsley for helpful comments. I also appreciate the comments of J. Vernon Henderson and Yannis M. Ioannides.

¹The incorrect sign has also been discovered by Clive Southey et al. (1990).

lation, the comparative-statics results for optimal housing consumption, \tilde{h}_c , housing investment, \tilde{h}_I , and savings, \tilde{S} , can be obtained by solving the following equation:²

$$(1) \quad \mathbf{D} \begin{bmatrix} d\tilde{h}_c \\ d\tilde{h}_I \\ d\tilde{S} \end{bmatrix} = \frac{\mathbf{b}_1}{2} \left(dy_1 - \frac{dy_2}{1+r} \right) + \frac{\mathbf{b}_2}{2} \left(dy_1 + \frac{dy_2}{1+r} \right)$$

where \mathbf{D} (the matrix given at the top of p. 382) is the Hessian obtained in differentiating the first-order conditions for \tilde{h}_c , \tilde{h}_I , and \tilde{S} , and

$$\mathbf{b}_1 = \begin{bmatrix} U_{11}R - E[V'']\tau(1+r) \\ U_{11}P_1 + E[V''P_2](1+r) \\ U_{11} + E[V''](1+r)^2 \end{bmatrix}$$

$$\mathbf{b}_2 = \begin{bmatrix} U_{11}R + E[V'']\tau(1+r) \\ U_{11}P_1 - E[V''P_2](1+r) \\ U_{11} - E[V''](1+r)^2 \end{bmatrix}$$

By using Cramer's rule and noticing that \mathbf{b}_1 is identical to the third column of \mathbf{D} , one knows immediately that both $d\tilde{h}_c$ and $d\tilde{h}_I$ are independent of the change in the income path, $dy_1 - dy_2/(1+r)$, but depend on the change in wealth, $dy_1 + dy_2/(1+r)$. However, $d\tilde{S}$ depends on the changes in both wealth and the path of income. The

²Where $P_1 = P - L - R$, and $P_2 = P(1+\theta) - L(1+r) - [T(\bar{u}) - \tau(\bar{u})]$. For comparison with the notation in the original paper, $P_1 = \xi/(1+r)$, and $P_2 = \beta + \gamma$.

$$\mathbf{D} = \begin{bmatrix} U_{11}R^2 + U_{22}f^2 + E[V'']\tau^2 & U_{11}RP_1 - E[V''P_2]\tau & U_{11}R - E[V'']\tau(1+r) \\ U_{11}RP_1 - E[V''P_2]\tau & U_{11}P_1^2 + E[V''P_2^2] & U_{11}P_1 + E[V''P_2](1+r) \\ U_{11}R - E[V'']\tau(1+r) & U_{11}P_1 + E[V''P_2](1+r) & U_{11} + E[V'']\tau(1+r)^2 \end{bmatrix}$$

solution to equation (1) yields:³

$$(2a) \quad d\tilde{h}_c = \frac{U_{11}}{D} \left\{ E[V''] E[V''(P_2 - (1+r)P_1)^2] - E^2[V''(P_2 - (1+r)P_1)] \right\} \times [R(1+r) + \tau](1+r) \left(dy_1 + \frac{dy_2}{1+r} \right)$$

$$(2b) \quad d\tilde{h}_I = -\frac{U_{11}U_{22}}{D} f^2 E[V''(P_2 - (1+r)P_1)] \times (1+r) \left(dy_1 + \frac{dy_2}{1+r} \right)$$

$$(2c) \quad d\tilde{S} = \frac{1}{2} \left(dy_1 - \frac{dy_2}{1+r} \right) + \frac{1}{2D_{-I}} \times \left\{ U_{11}U_{22}f^2 - U_{11}E[V''] \times [R^2(1+r)^2 - \tau^2] - U_{22}f^2E[V'']\tau(1+r)^2 \right\} \times \left(dy_1 + \frac{dy_2}{1+r} \right) - \left\{ P_1 + \frac{1}{D_{-I}} (U_{11}[R(1+r) + \tau]R + U_{22}f^2(1+r)) \right\} \times E[V''(P_2 - (1+r)P_1)] \Big\} d\tilde{h}_I$$

where

$$D = U_{11}U_{22}f^2E[V''(P_2 - (1+r)P_1)^2] + \{U_{11}[R(1+r) + \tau]^2 + U_{22}(1+r)^2f^2\} \times \{E[V'']E[V''(P_2 - (1+r)P_1)^2] - E^2[V''(P_2 - (1+r)P_1)]\}$$

is the determinant of \mathbf{D} and where

$$D_{-I} = U_{11}U_{22}f^2 + U_{11}E[V''] [R(1+r) + \tau]^2 + U_{22}f^2E[V'']\tau(1+r)^2$$

is the determinant of a reduced \mathbf{D} (with its second row and second column removed) and is positive.

The correct comparative-statics result for \tilde{S} , shown by equation (2c), indicates that savings will change to offset the change in the income path and that, given the income path, it will also change directly with wealth, since the income elasticities of consumption in the two periods are, in general, not equal. Furthermore, \tilde{S} has to decrease to meet the increased demand for housing investment as wealth increases. The positive relationship between housing investment demand and wealth is indicated by equation (2b). Let $A = -V''/V'$ be the coefficient of absolute risk aversion. Using a first-order condition,

$$(3) \quad E[V'(P_2 - (1+r)P_1)] = 0$$

and substituting AV' for $-V''$ in (2b), it can be shown that $d\tilde{h}_I/d(y_1 + y_2/(1+r))$ is positive if $dA/dW < 0$ and that it is 0 for $dA/dW = 0$, where W is the second-period

³It can be shown that (2a) is equivalent to equation 17b in Henderson and Ioannides (1983).

wealth.⁴ In other words, the housing investment demand increases with wealth if the coefficient of absolute risk aversion is decreasing. The investment demand remains unchanged if wealth is unchanged or if the coefficient of absolute risk aversion is constant.

Further insights into the determinants of housing investment demand may be obtained from equation (3). Using a linear approximation for V' at $\bar{\theta} = E[\theta]$, one obtains the following:⁵

$$(4) \quad P\bar{h}_1 \approx \frac{E[P_2 - (1+r)P_1]}{PA \text{Var}(\theta)}.$$

Equation (4) shows that the value of housing investment is determined by three factors: the expected rate of return on housing investment ($E[P_2 - (1+r)P_1]/P$), the coefficient of absolute risk aversion, and the investment risk ($\text{Var}(\theta) = \text{Var}\{E[P_2 - (1+r)P_1]/P\}$). In other words, investment housing in this model plays a role, not as a savings vehicle, but as a risky asset which offers an opportunity for people to trade risk-bearing for a higher return. Housing investment demand is affected by wealth only because wealth affects people's willingness to bear risks. The path of income affects neither housing investment demand nor housing consumption demand, because a perfect financial market, in which personal saving and borrowing are unrestricted,

is assumed in the model. With restrictions on personal saving and borrowing, both consumption and investment demands could be affected by the income path.

II. Conclusions

The finding in Henderson and Ioannides (1983) is counterintuitive and unsupported empirically. Indeed, Henderson and Ioannides (1987) find that the likelihood of owning a home is a positive function of lifetime wealth. They attribute the discrepancy between theoretical and observed patterns of housing tenure choice to such factors as taxes, capital market imperfections, and rental externalities. My results show that both housing consumption and investment demands may increase with wealth and, thus, that it is not necessary to rely upon those institutional and externality factors to produce a positive wealth effect on owning a home. Whether or not wealthier people are more likely to own the housing they consume depends on the magnitude of the income elasticity of housing consumption demand relative to that of housing investment demand, which in turn depends on the rate at which risk aversion decreases with wealth. If the income elasticity of investment demand exceeds that of consumption demand, then wealthier people are more likely to be owner-occupiers.

THE purpose of the American Economic Association, according to its charter, is the encouragement of economic research, the issue of publications on economic subjects, and the encouragement of perfect freedom of economic discussion. The Association as such takes no partisan attitude, nor does it commit its members to any position on practical economic questions. It is the organ of no party, sect, or institution. People of all shades of economic opinion are found among its members, and widely different issues are given a hearing in its annual meetings and through its publications. The Association, therefore, assumes no responsibility for the opinions expressed by those who participate in its meetings. Moreover, the papers presented are the personal opinions of the authors and do not commit the organizations or institutions with which they are associated.

Editors' Introduction

This volume contains the *Papers and Proceedings* of the one hundred and third annual meeting of the American Economic Association. The *Proceedings* record the business activities of the Association in 1990; the annual membership meetings; the March and December meetings of the Association's officers and committees. The *Papers* constitute the greater part of the volume. They comprise contributions that fill roughly the same number of pages as two regular issues of the *American Economic Review*. We would like to take this opportunity to answer a number of commonly asked questions about the *Papers*.

Who chooses the authors? About a year in advance, the Association's President-elect, acting as program chairman, decides on the theme of the sessions and topics for which sessions will be organized. This is done after consultation and comment, both volunteered and solicited, from a wide range of individuals. (A *Call for Papers* was published annually in the Notes section of the *AER*, and now appears in the Fall issue of the *Journal of Economic Perspectives*.) The President-elect invites persons to organize these sessions. Each session organizer in turn invites several persons (usually two or three) to give papers on the theme of the session, and asks others to give comments on the papers. The program chairman decides at the time of organization which sessions will be included in this volume. Space limitations restrict the number of printed sessions. This year we are printing 22 sessions, although a total of 132 sessions were sponsored, either solely by the American Economic Association or jointly with other allied societies.

Are discussants' comments published? There has been no standard practice with regard to the publication of comments and discussions in the past. This year the President-elect decided to publish one set of

comments for one panel session. For the other sessions, names and affiliations of commentators are printed at the start of each session, permitting readers especially interested in particular comments to write to the commentator for a copy of the discussion.

What standards must the papers meet?

The guidelines under which papers are published in the *Papers and Proceedings* differ considerably from those governing regular issues of the *Review*. First, the length of papers is strictly controlled. Except in unusual circumstances they must be no more than twelve typescript pages in three-paper sessions, and eighteen typescript pages in two-paper sessions. Second, papers are not subjected to a formal refereeing process. However, a paper can be rejected if, after reading it, we conclude it is utterly without merit. This year we are pleased to report that no paper has been rejected on this ground. Third, their content and range of subject matter reflect the wishes of the President-elect to investigate and expose the current state of economic research and thinking. In most cases they are therefore exploratory and discursive, rather than formal presentations of original research.

In order to produce this volume by May, strict deadlines must be met and there is no time for communication with every author about editing changes made in order to improve content and style, and to satisfy space restrictions. Every effort is made to notify an author prior to the deadline if the paper is too long, or does not satisfy other specifications.

This year, authors for the most part were quite cooperative, and for this we are grateful.

RONALD L. OAXACA
WILMA ST. JOHN

Foreword

I could not have done my part in arranging the program for the 1990 annual meeting of the American Economic Association without the generous and proficient help of a number of people.

The staff of the American Economic Association and the Allied Social Science Associations in Nashville, responsible for negotiating with hotels and airlines, scheduling and fitting nearly 500 sessions into appropriate rooms with appropriate equipment, arranging dozens of functions to be catered, answering inquiries and publishing a faultless and informative catalogue, performed in a manner that I can only describe as heroic.

The editorial staff of the *AER Papers and Proceedings* has been helpful and patient as well as skillful. I offer them my thanks, and thanks also to a Program Committee that refereed approximately 400 submitted abstracts, selecting nearly a hundred and organizing them, with chairs and discussants, into proper sessions. They are: Henry J. Aaron, Robert Z. Aliber, Elizabeth E. Bailey, Joel Darmstadter, Paul A. David, Robert E. Dorfman, Richard Freeman, Lawrence B. Krause, Mancur Olson, Dwight H. Perkins, William Poole, Isabel V. Sawhill, David A. Wise, and Richard J. Zeckhauser.

THOMAS C. SCHELLING

RICHARD T. ELY LECTURE

Procrastination and Obedience

By GEORGE A. AKERLOF*

In this lecture I shall focus on situations involving *repeated* decisions with time inconsistent behavior. Although each choice may be close to maximizing and therefore result in only small losses, the cumulative effect of a series of repeated errors may be quite large. Thus, in my examples, decision makers are quite close to the intelligent, well-informed individuals usually assumed in economic analysis, but cumulatively they make seriously wrong decisions that do not occur in standard textbook economics.

This lecture discusses and illustrates several "pathological" modes of individual and group behavior: procrastination in decision making, undue obedience to authority, membership of seemingly normal individuals in deviant cult groups, and escalation of commitment to courses of action that are clearly unwise. In each case, individuals choose a series of current actions without fully appreciating how those actions will affect future perceptions and behavior. The standard assumption of rational, forward-looking, utility maximizing is violated. The nonindependence of errors in decision making in the series of decisions can be explained with the concept from cognitive psychology of undue salience or vividness. For example, present benefits and costs may

have undue salience relative to future costs and benefits.

Procrastination occurs when present costs are unduly salient in comparison with future costs, leading individuals to postpone tasks until tomorrow without foreseeing that when tomorrow comes, the required action will be delayed yet again. Irrational obedience to authority or escalation of commitment occurs when the salience of an action today depends upon its deviation from previous actions. When individuals have some disutility for disobedience and a leader chooses the step sizes appropriately, individuals can be induced to escalate their actions to extraordinary levels; the social psychologist Stanley Milgram (1975) led subjects to administer high levels of electrical shock to others in fictitious learning experiments. The subjects were induced into actions that were contrary to their true moral values. In the latter half of the lecture I will give examples to illustrate how sequences of errors, each error small at the time of the decision, cumulate into serious mistakes; these decisions also illustrate how laboratory conditions of isolation, carefully engineered in the Milgram experiment and necessary for the type of behavior he induced, in fact commonly occur in nonexperimental situations. Thus the sequences of errors that are the subject of this lecture are not rare and unusual, only obtainable in the laboratory of the social psychologist, but instead are common causes of social and economic pathology.

Although an analysis of behavioral pathology might initially appear to be outside the appropriate scope of economics, I shall argue that, in important instances, such pathology affects the performance of individuals and institutions in the economic and social domain. Examples include the poverty

*Department of Economics, University of California, Berkeley, CA 94720. SES 90-09051 administered by the Institute for Business and Economic Research at the University of California-Berkeley.

of the elderly due to inadequate savings for retirement, addiction to alcohol and drugs, criminal and gang activity, and the impact of corporate "culture" on firm performance. Economic theories of crime, savings, and organizations are deficient and yield misleading conclusions when such behavior is ignored. The behavioral pathologies that I will describe also have consequences for policies toward, for example, savings, substance abuse, and management.

Individuals whose behavior reveals the various pathologies I shall model are not maximizing their "true" utility. The principle of revealed preference cannot therefore be used to assert that the options that are chosen must be preferred to the options that are not chosen. Individuals may be made better off if their options are limited and their choices constrained. Forced pension plans may be superior to voluntary savings schemes; outright prohibitions on alcohol or drugs may be preferable to taxes on their use reflecting their nuisance costs to others; and an important function of management may be to set schedules and deadlines and not simply to establish "appropriate" price-theoretic incentive schemes to motivate employees.

I. Salience and Decisions

A central principle of modern cognitive psychology is that individuals attach too much weight to salient or vivid events and too little weight to nonsalient events. Richard Nisbett and Lee Ross (1980) describe the following thought experiment, that they consider the "touchstone" of cognitive psychology, just as the shifting of a supply or a demand curve is the central thought experiment of economics.

Let us suppose that you wish to buy a new car and have decided that on grounds of economy and longevity you want to purchase one of those stalwart, middle-class Swedish cars—either a Volvo or a Saab. As a prudent and sensible buyer, you go to *Consumer Reports*, which informs you that the consensus of their experts is that

the Volvo is mechanically superior, and the consensus of the readership is that the Volvo has the better repair record. Armed with this information, you decide to go and strike a bargain with the Volvo dealer before the week is out. In the interim, however, you go to a cocktail party where you announce your intention to an acquaintance. He reacts with disbelief and alarm; "A Volvo! You've got to be kidding. My brother-in-law had a Volvo. First, that fancy fuel injection computer thing went out. 250 bucks. Next he started having trouble with the rear end. Had to replace it. Then the transmission and the clutch. Finally sold it in three years for junk."

[quoted in Nisbett and Ross, p. 15;
from Nisbett, et al., 1976, p. 129]

The status of this additional information is only to increase the *Consumer Reports* sample by one. Mean repair records are likely to remain almost unchanged. Yet Nisbett and Ross argue that most prospective car buyers would not view the new information so complacently.

An experiment by Eugene Borgida and Nisbett (1977) confirms the intuition that salient information exerts undue influence on decisions. Freshmen at the University of Michigan with a declared psychology major were chosen as subjects. Students were asked to express preferences concerning psychology electives. Before making this decision, a control group was given only mean psychology course evaluations; others were, in addition, exposed to a panel discussion by advanced psychology majors selected so that their course evaluations corresponded to the mean. As in the Volvo thought experiment, vivid information played a greater role than pallid information; compared to the control group, those exposed to the panel chose a higher fraction of courses rated above average. To counter the argument that this bias might be due to thoughtlessness because of the unimportance of the decision, Borgida and Nisbett note that the bias was greater for those who later entered the major than for those who dropped out.

II. Procrastination

Procrastination provides the simplest example of a situation in which there are repeated errors of judgment due to unwarranted salience of some costs and benefits relative to others. In this case each error of judgment causes a small loss, but these errors cumulatively result in large losses over time and ultimately cause considerable regret on the part of the decision maker.

Let me illustrate with a personal story and then show how such behavior can be modeled. Some years back, when I was living in India for a year, a good friend of mine, Joseph Stiglitz, visited me; because of unexpected limitations on carry-on luggage at the time of his departure, he left with me a box of clothes to be sent to him in the United States. Both because of the slowness of transactions in India and my own ineptitude in such matters, I estimated that sending this parcel would take a full day's work. Each morning for over eight months I woke up and decided that the *next* morning would be the day to send the Stiglitz box. This occurred until a few months before my departure when I decided to include it in the large shipment of another friend who was returning to the United States at the same time as myself.

The preceding story can be represented mathematically in the following way. The box was left with me on day 0. At the end of the year, at date T , the box could be costlessly transported. The cost of sending the box on any day prior to T was estimated at c , the value of a day's work. I estimated Joe's valuation of the use of the contents of the box (which was the same as my value of his use of the contents) at a rate of x dollars per day. I saw no reason to attach any discount rate to his use of the box. However, each day when I awoke, the activities I would perform if I did not mail off the Stiglitz box seemed important and pressing, whereas those I would undertake several days hence remained vague and seemed less vivid. I thus overvalued the cost of sending the box on the current day relative to any future day by a factor of δ . This caused me to procrastinate.

On each day t , until date $T - c/x$, I made the dynamically inconsistent decision that I would not send the box on that day, but would instead send it the very next day. Ultimately, I decided to simply wait and send it costlessly at my departure.

Consider my decision process. On each day t , I awoke and made a plan to send the box on date t^* . I chose t^* to minimize V , the costs net of the benefits of sending the box.

If I sent the box on that day (day t), V would be

$$(1) \quad V = c(1 + \delta) - (T - t^*)x$$

for $t^* = t$.

The factor δ represents the extra salience of sending the box on that day. If I waited, but sent the box at some later time, other than the time of my departure, V would be

$$(2) \quad V = c - (T - t^*)x$$

for $t + 1 \leq t^* < T$.

And if I waited until the end of my stay to send the box, I saw that

$$(3) \quad V = 0 \quad \text{for } t^* = T.$$

On each and every day, up until day $T - c/x$, the time when the costs of sending the box just equaled the benefits of its receipt, I decided to send the box *tomorrow*. Since δc was sufficiently large, at each date t , I set the planned date for sending the box at $t^* = t + 1$. By time $T - c/x$, it was apparent that the costs of sending the box no longer exceeded the benefits, and thus I guiltily decided to ship it at the time of my return. I had procrastinated too long.

Three key features of the situation resulted in procrastination. First, the time between decisions was short. Second, in each period there was a small, but not a minuscule, "salience cost" to undertaking the job now rather than later. The condition that results in procrastination is $\delta c > x$. The daily benefit from the box, x , is small if the

time between decisions is short. δc is significant if there is a significant psychological lump sum cost to doing the project now rather than later. The third key feature of the situation was the dynamic inconsistency in my decision making. Each day I decided to put off the project until tomorrow. I did not have rational expectations, since I did not foresee that when the next day came I would continue to put off the decision for an additional day.

My procrastination was costly. The cumulative loss incurred due to my procrastinating behavior amounted to approximately $Tx - c$.¹ For each day up to the critical day at approximately $T - c/x$, I wrongly decided not to send the box. After the critical time (approximately) $T - c/x$, I made the correct decision to wait to send the box.² For every day between 0 and $(T - c/x)$, the loss from the decision made on that day was x , the cost of an extra day's use of the box. The cumulative loss was consequently the product of the daily cost of a delay, x , and the $(T - c/x)$ decisions to delay. This product is $Tx - c$, the total loss from the failure to send the box. In consequence, the cumulative cost of the errors of decision amount to the total loss that occurs over the period. Many wrong decisions all of the same type but of small value cumulated into a significant loss. And yet this loss occurred as a consequence of only a modest amount of irrationality or "undue salience."

A numerical example is useful to illustrate the necessary size of the "salience" premium δ on current relative to future work required for procrastination to occur. Suppose that I valued my time at \$50 per day and Joe Stiglitz' use of his box at 50 cents per day. If δ exceeds .01 ($= .50/50$), then procrastination will occur for 265 ($= 365 - 50/.5$) days. We consequently see that in this type of example, where there are

significant initial costs relative to the benefits, only small amounts of unwarranted salience on present relative to future action can result in significant delay.

Procrastination with Deadlines. The preceding model of procrastination has the special feature that if the task is not done in a timely fashion, it does not need to be done at all. It is like the referee's report that the editor angrily sends to another reviewer after too long a lapse. However, many tasks have deadlines. For our students, the cost of procrastination involves "pulling an all-nighter" to get the term paper (conference paper) done on time.

Qualitatively, the same type of results that we have already seen can still occur: small salience costs to beginning projects can result in costly procrastination. Consider what happens if the disutility of a project varies with the square of hours worked per day, and the number of hours to complete a project is fixed. Let the salience cost of beginning a project be a multiple of the disutility of the first day's work. In an example in which the salience cost is 2 percent of the total cost and the length of the project is 100 days, the added cost of completing the project can be calculated at approximately 41 percent.³

³Let us suppose that the daily utility cost of doing a project varies with the square of the number of hours worked per day, and that the project, without procrastination, would require Th hours of labor. Then we can write the intertemporal utility function as $U = \sum_{t=0}^T e_t^2$, where e_t is the number of hours worked on day t . Without procrastination, the total utility cost of the project is $U = Th^2$.

Let us now compare this to the cost borne by a procrastinator. For the procrastinator, current costs are unduly salient in comparison with future costs. The salience premium is δh^2 , a multiple of δ of the daily cost of the project if begun on time. The perceived cost of completing the project, if begun at date τ , is thus:

$$V = \delta h^2 + \sum_{t=\tau}^T e_t^2.$$

In each period, the procrastinator compares the total cost V of the project if begun that day (including the added salience cost δh^2 of that day's input) with the cost of waiting one more day to begin, taking no

¹The exact loss is $Tx - c(1 + \delta)$. If I sent the box on date 0, V has value $c(1 + \delta) - Tx$. Since I sent the box at T , $V = 0$. The difference is $Tx - c(1 + \delta)$.

²The exact critical date is the first day on which the decision maker decides to send at T : i.e., the smallest t such that $c - (T - t - 1)x > 0$.

It may also be worth noting that if the salience value of beginning the project increases with the intensity of the first period's work, a project, such as a reducing diet, may never be begun, or a task may be begun at the latest possible date at which completion is feasible.

III. Procrastination: Substance Abuse, Savings, and Organizational Failures

At first glance, my examples of procrastination may appear to be of no relevance to economics. However, I want to argue that such behavior may be critical in understanding the causes of such varied problems as drug abuse, inadequate savings and some types of organizational failure.

A. Substance Abuse

It has often been observed that consumers are knowledgeable about their decisions, and that their decisions are utility maximizing. Ethnographies of drug users suggest that drug use is no exception. Gary Becker and Kevin Murphy (1988) and George Stigler and Becker (1977) have developed the theory of such behavior in their forward-looking models of rational addiction. In these models, use of a good affects the future enjoyment of its consumption, but people correctly foresee these changes in taste. The application of such models, combined with utilitarian ethics, leads to the conclusion that drug use should be legalized with a tax reflecting its nuisance to others.

account that when the next day arrives, it too will have special salience. Behaving in this way, the project is begun with approximately $T\delta^{-1/2}$ days left for its completion. This is a poor approximation for low values of δ because for low values of δ , it does not pay to procrastinate. This increases the total cost of the project by a multiple that is the square root of δ . In this example, a small salience cost of beginning a project results in losses from future actions that are a multiple of the cost. For example, if T is 100 days and δ is 2, the salience cost of beginning the project relative to the total nonprocrastinating cost is only .02. But the total cost of completing the project increases by 41 percent ($\sqrt{2} - 1$).

I do not agree with this conclusion, because I do not agree that the model of forward-looking, rational behavior accurately describes the way in which individuals decide on drug or alcohol intake. Most drug abusers, like most chronically overweight individuals, fully intend to cut down their intake, since they recognize that the long-run cost of their addiction exceeds its benefits. They intend to stop—tomorrow. Individuals following the procrastination model are both maximizing and knowledgeable, and yet their decisions are not fully rational. For example, psychologist Roger Brown describes addictions in the following way.

Actions like smoking a cigarette, having a drink, eating a candy bar, and working overtime to "catch up" all lead to immediate and certain gratification, whereas their bad consequences are remote in time, only probabilistic, and still avoidable now. It is no contest: Certain and immediate rewards win out over probabilistic and remote costs, even though the rewards are slight and the possible costs lethal. [1986, p. 636]

Ethnographies of drug abusers reveal that most are well aware of the long-term consequences of their habit and many have detailed and subtle knowledge of the effects of drugs. (See, for example, Cheryl Carpenter et al., 1988 and Harvey Feldman et al., 1979.) They apply this knowledge to avoid some of the worst potential consequences of drug use. An interview with Don, an "angel dust" (PCP) user in the Seattle-Tacoma area reveals the knowledge of the long-term effects of drug use, and also an inability to use the knowledge to quit. Don tells his interviewer:

And every time I use the drug and I come down and I am straight, since I do have this heightened form of awareness and perspective, I always tell myself, "Well, that's the last time I'll use it. I don't need it now." I can see where this is, what I've got to do, and this is what I want to do and everything falls into place.

[Feldman et al., p. 137]

Later, I will discuss some ways in which the social pressures emanating from group dynamics reinforce individual reasons for addiction.

B. Savings

The procrastination model may also pertain to intertemporal savings and consumption decisions. The modern textbook/journal article model of consumption and savings decisions typically views agents as maximizing a time-separable utility function with discount rate δ . This discount is said to parameterize agents' impatience. Curiously, economists who build models with utility functions of this sort consider themselves to be modeling the behavior of *rational* consumers. Yet early discussion of impatience viewed discounting as *irrational* behavior. Irving Fisher regarded such impatience as evidence of lack of foresight or lack of will. In this regard, he writes,

Generally speaking, the greater the foresight, the less the impatience and *vice versa* This is illustrated by the story of the farmer who would never mind his leaking roof. When it rained he could not stop the leak, and when it did not rain there was no leak to be stopped! Among such persons, the preference for present gratification is powerful because their anticipation of the future is *weak*. [1930, p. 81]

Fisher's example of the farmer fits the model of an agent continually making an inconsistent decision.

A clear moral of the procrastination model is that time-inconsistent behavior is especially apt to occur when there is some fixed cost (perhaps not very great) to beginning a task, the "periods" are short, and the per period cost of delay is low. Many personal financial decisions satisfy these conditions. A good example concerns the behavior of junior faculty at Harvard. Due to some institutional oddity, university contributions to TIAA/CREF cumulated without payment of interest until the recipient filed a form indicating his desired allocation between the two retirement funds. This could

be done at any time and took less than an hour. And yet most junior faculty who left Harvard in the 1970's made this decision only upon their departure. They thus lost hundreds of dollars worth of interest by failing to do an hour's work.⁴

A more serious application of the procrastination model is to savings.⁵ Most of the U.S. elderly (those over 65) derive relatively little of their income from financial assets. In 1971, 51 percent of the elderly had no income from financial assets; 78 percent had less than 20 percent of their income from financial assets (Michael Hurd, 1990, p. 571). This stark absence of financial asset income is consistent with the hypothesis that most households would save very little, except for the purchase of their home and the associated amortization of mortgage principal, in the absence of private pension plans. Partly because these additions to financial assets are so small, some seemingly paradoxical results have been obtained. Phillip Cagan (1965) and George Katona (1965), for example, find a *positive* relation between pension plans and private saving. In the life cycle model (up to some limit), \$1 of pension savings should lead to \$1 reduction of private saving. Steven Venti and David Wise (1986, 1987) report results similar to those of Cagan and Katona. They find no significant relation between ownership of a pension plan and willingness to invest in IRAs. Alicia Munnell's (1976) findings are less extreme. She looked at the savings of a sample of 5,000 men aged 45 to 59 in 1966. She estimated that a \$1 private

⁴I owe this observation to Janet Yellen.

⁵Richard Thaler and Hershey Shefrin (1981) discuss the role of Christmas Clubs in forcing the scheduling of savings. Their model of saving behavior, and of procrastination, is different from my model in this lecture. Their model discusses two types of decision making: for long-term planning and for maximization of current utility. People may constrain themselves (i.e., may make arrangements such as Christmas Clubs) so that they can then be free to maximize their short-term utility without further constraint. In this way budgets act as mental accounts. The Christmas Clubs relative to my model set clear schedules for saving, which result in penalties if not followed, and thereby prevent procrastination.

pension contribution caused a reduction in nonpension savings of 62¢ for these men nearing retirement. This is still considerably less than the \$1 that would be expected if people were life cycle savers and pension plans did not induce oversaving.⁶

The hypothesis that, in the absence of pension plans, many individuals lack sufficient self-discipline to begin saving for retirement in a timely fashion is consistent with the finding that there were high rates of elderly poverty prior to the rapid, unexpected growth in Social Security payments in the late 1960's and the 1970's. In 1966, the elderly poverty rate was 30 percent, fully double the poverty rate of the nonelderly (David Ellwood and Lawrence Summers, 1986, p. 81).⁷

C. Organizational Failures

Procrastination is as prevalent in the workplace as in the home. Procrastination by workers results both in delay in initiating projects that should be begun as well as in delay in terminating projects that should be ended.⁸

⁶It is also low because we might expect those without pension plans to be making up for prior failure to save as they near retirement, just as the procrastinating student has to work especially hard near his term paper deadline.

⁷This high rate may reflect the prior lives of poverty of the elderly population in 1966; this group spent much of their working lives in the Great Depression. But earlier statistics, from such indicators as the fraction of elderly living in poorhouses, show that the elderly had particularly high poverty rates in the 1920's, before both modern pension plans and the Great Depression (Michael Dahlin, 1983).

⁸In their advice book on *Procrastination*, Jane Burka and Lenora Yuen (1983) urge potential procrastinators to set clear and realistic schedules for themselves and then adhere to them. In the preceding Stiglitz-box model, the determination of a schedule that was binding would have resulted in the box being sent on day 1 or day 2. Thomas Schelling (1985, p. 368) has explained in similar terms why parents at the beach may give their children the clear advice not to go in the water at all, even though they do not mind the children getting a little bit wet. In the absence of a clear "schedule" telling the children when the water is too deep, they may wade ever deeper and end up in danger.

In private life, individuals are frequently forced to self-monitor their behavior, as in stopping an addiction, writing a Ph.D. thesis, devising a private asset plan, or sending off referee reports; in such areas procrastination can easily occur leading to serious losses. However, in work situations, outside monitoring is possible, and a major function of management is to set schedules and monitor accomplishment so as to prevent procrastination.

Proper management not only prevents procrastination in project *initiation*; it also prevents procrastination in project *termination*. Psychologists have found tendencies to delay terminations of projects by people who consider themselves responsible for their initiation. Barry Staw (1976) divided a group of 240 undergraduate business students into two groups. One group was asked to decide on investment allocation in a business school case study of the Adams and Smith Corporation. They were then asked to make a further allocation of investment between the division with their initial project and the other division of the firm. In contrast, a control group only had to make the second allocation. Both groups, however, had matched past histories of the firm and the success of the firm's projects. In the case of project failure, those who had made a prior commitment wanted to invest significantly more in that division than the control group with the same matched history who had made no such prior commitment. One explanation matches our model: that failure to terminate the project puts the painful decision off until tomorrow; the pain of admitting a mistake today is salient relative to the pain of having to admit a possibly even bigger mistake tomorrow. This same phenomenon may also be explained, not necessarily inconsistently, by cognitive dissonance. Once people have made decisions, they avoid information that does not support that decision because it is psychologically painful.

Staw and S. McClane (1984) report how the commercial division of a large American bank avoids procrastination in loan cutoff decisions. Loan officers are not penalized for cutting off loans, although they are pe-

nalized for failing to foresee possible losses. They are especially penalized if loan losses are discovered by bank examiners before they are reported. Most important, loans with significant difficulties are referred to a separate committee not involved in the initial decision to obtain the maximum salvage value.

In the next section I will discuss how courses of action are reinforced by selective elimination of information contrary to that course of action, so that initial psychological overcommitments are reinforced. Jerry Ross and Staw (1986) examine the history of Expo 86 in Vancouver, whose projected losses escalated from a maximum of \$6 million to over \$300 million. In this case, exit costs reinforced the initial psychological overcommitment: the Prime Minister of British Columbia feared loss of election on termination, contracts would have to be breached, and outside vendors would make losses from investments made in anticipation of the fair.

Staw and Ross (1987) list management practices that limit overcommitment: administrative turnover; low cost to executives for admitting failure; lack of ambiguity in data regarding performance; allowing losses to be blamed on exonerating circumstances; separating termination decisions from initiation decisions; and considering from the beginning the costs and procedures of project termination.

IV. Indoctrination and Obedience

Irrational obedience to authority is a second type of "pathological," time-inconsistent behavior with important social and economic ramifications. Procrastination occurs when there is a fixed cost of action today and current costs are more salient than future costs. Undue obedience to authority may occur as a form of procrastination if disobedience of an authority is salient and distasteful. In addition, authority may be particularly powerful when yesterday's actions affect the norms of today's behavior. Both such influences (the salience of current disobedience and a shift in the utility of subjects in accordance with their prior actions) are present in Milgram's experiments, which I shall review.

The subjects in the Milgram experiment were adult males, recruited by a mail circular requesting participation in an experiment purportedly concerning the effects of punishment on memory. The subjects were assigned the role of teacher, while an accomplice of the experimenter, a professional actor, played the role of learner. The subjects were instructed to administer shocks to the learner when he gave wrong answers. The shocks were a learner-discipline device. The learner, a trained actor instructed to simulate the appropriate reactions to the shocks administered by the subjects, was visible to the subject through a glass window, and, unbeknownst to the subject, was not wired. Subjects initially gave low voltage shocks (15 volts) with doses increasing 15 volts at a time to a maximum of 450. There are different versions of this experiment, but, in all versions, the learner showed significant response to the shocks. For example, in one version, according to Milgram's description, "at 75 volts the learner began to grunt and groan. At 150 volts he demands to be let out of the experiment. At 180 volts he cries out that he can no longer stand the pain. At 300 volts he ... [insists] he must be freed" (1965, p. 246, quoted in E. Stotland and L. K. Canon, 1972, p. 6). Despite these protests by the learner, 62.5 percent of the subjects reached the maximum of 450 volts. The experiment has been repeated under a wide variety of conditions, but always with the same result: a significant fraction of the population administers the maximum dosage.

As important as the primary finding from Milgram's experiment that individuals are remarkably obedient is the further finding of their lack of awareness of this trait in themselves and in others. Elliot Aronson (1984, p. 40), a professor of social psychology at UC-Santa Cruz, asks the students in his classes how many would continue to administer shocks after the learner pounds on the wall. Virtually no one responds affirmatively. Milgram conducted a survey of psychiatrists at a major medical school who predicted that most subjects would not administer shocks in excess of 150 volts, and virtually no subjects would administer the maximum 450 volts. This finding supports

my central argument: that in appropriate circumstances, people behave in time-inconsistent ways that they themselves cannot foresee, as when they procrastinate or exhibit irrational obedience to authority.

A Model of Behavior in the Milgram Experiment. Let me present a simple model that is a variant of the previous model of procrastination and which explains the sequential decisions made by the subjects in Milgram's experiment. I shall first assume that current disobedience by the subject is especially painful; it is especially salient. Lee Ross (1988) has argued that special salience is attached to disobedience because there is an implicit contract between the teacher and the experimenter. The experiment defines the situation so that there is no legitimate way for the teacher to terminate.⁹ Thus the subject sees the cost of current disobedience as very high, although in an ill-defined way, he may plan to disobey in the future. Second, I shall assume that the subject suffers a loss in utility, not based on the current voltage he administers to the learner, but instead on the deviation of the current voltage from what he last administered. (Alternatively his utility might depend on the deviation from the highest voltage previously administered.) This model is consistent with cognitive dissonance. Once people have undertaken an action, especially for reasons they do not fully understand, they find reasons why that action was in fact justified. In this formulation, the subject decides to obey up until time T so as to maximize V_t .

If he disobeys today at time t , his utility is

$$(4) \quad V_t = -bD(1 + \delta).$$

But if he postpones obeying, his expected utility is

$$(5) \quad V_t = -bD - c \sum_{k=t}^{T-1} (W_k - W_{t-1})$$

$T \geq t + 1$

⁹Ross suggests that if teachers had a red button to push that would allow them to stop the experiment, very few subjects would have given the maximum dosage. In my model, this would decrease the value of δ , the special salience attached to current disobedience.

if he first disobeys at time $T \geq t + 1$, where δ is the extra salience attached to today's disobedience, D is the cost of disobedience, W_k is the voltage of the shock administered at time k , and W_{t-1} is the norm for the level of shocks determined by previous actions.

It can easily be seen in this formulation that at each date, with sufficiently slow expected future escalation of commands the subjects can be led, as in the Milgram experiment, to deliver ever-higher levels of shock. They plan to disobey in the future if the experiment continues, but not currently. While planning future disobedience if escalation continues, at the same time these subjects are continuing to raise the level of shock required to induce them to disobey. The dependence of norms of behavior on previous actions does not just cause continued poor decision making due to postponement, but also causes escalating errors in decisions.

While V may be the function that subjects maximize in the heat of the moment, under the conditions of the Milgram experiment, a more accurate expression of their *true* intertemporal utility function might be

$$(6) \quad V_0 = \sum_k \{ -bD_k - cW_k \}$$

where V_0 is their intertemporal utility and k sums over all the trials.

Such a utility function is reflected in the postexperiment interviews and follow-up questionnaires. Most of the subjects were, in retrospect, extremely regretful of their decisions in the experiment. For example, one subject, who was a social worker, wrote in a follow-up questionnaire a year later:

What appalled me was that I could possess this capacity for obedience and compliance to a central idea, i.e. the value of a memory experiment, even after it became clear that continued adherence to this value was at the expense of the violation of another value, i.e. don't hurt someone else who is helpless and not hurting you. As my wife said, "You can call yourself Eichmann."
[Milgram, 1975, p. 54]

The preceding models of procrastination and obedience concern actions that occur because individuals possess cognitive structures of which they are less than fully aware. The assumption that such structures influence behavior is unfamiliar in economics, but central to other social sciences. A major task of psychology is to discover such unperceived behavioral regularities; the concepts of *culture* in anthropology and *the definition of the situation* in sociology both concern cognitive structures only dimly perceived by decision makers.

The Milgram experiment demonstrates that isolated individuals can exhibit remarkably obedient (and deviant) behavior inside the laboratory. In group situations, however, there is evidence that such behavior occurs only when there is near unanimity of opinion. In this regard, the most relevant evidence comes from a variant of the Asch experiment. Solomon Asch (1951, p. 479) found that subjects asked to match the length of a line to a comparison group of lines of different length gave the wrong answer roughly 40 percent of the time if they were preceded by confederates of the experimenter who had previously given the wrong answer. However, in another variant of the experiment, Asch (1952) found that the presence of just a single confederate who gave the right answer in a large group of confederates reduced the number of wrong answers by a factor of two-thirds. This suggests that the presence of like-minded others significantly raises the likelihood of disobedience in situations such as the Milgram experiment. It might be inferred that obedience such as obtained by Milgram could only occur in the laboratory where people are shielded from outside information and influences.

The next four sections will present examples of individuals who participate in groups and make regrettable decisions. In each of the examples, a sequence of small errors has serious ill consequences. Furthermore, in each of the situations described, there is a natural equilibrium in which those who disagree with the actions taken find it disadvantageous to voice their dissent, which is accordingly isolated from the decision-making process.

V. Cults

A. Unification Church

Evidence seems to show that neither members nor inductees into cult groups such as the Unification Church (Moonies) are psychologically very much different from the rest of the population (see Marc Galanter et al., 1979; and Galanter, 1980). The method of induction into the Moonies indicates how normal people, especially at troubled times in their lives, can be recruited into cults and the cult can persist. Membership into the Moonies involves four separate decisions. Potential recruits are first contacted individually and invited to come to a 2-day, weekend workshop. These workshops are then followed by a 7-day workshop, a 12-day workshop, and membership. The potential recruit in consequence makes four separate decisions: initially to attend the 2-day workshop, to continue into the 7-day workshop, and then again into the 12-day workshop, and finally to join the Church. As in the Milgram experiment, the membership decision is achieved in slow stages.

Consider the process from the point of view of the potential recruit. Those who agree to attend the first 2-day workshop must have some predisposition toward the goals of the Church; otherwise they would not have attended. But they are probably surprised on arrival to find so many like-minded persons. In addition, the members of the Church intermingle and apply gentle persuasion in the first 2-day workshop; the inductees' commitment at this point begins to change. Then, continuing with the 7-day workshop, and again with the 12-day workshop, only the most committed continue; those who disagree leave. At each stage the Church members are thus able to increase the intensity of their message. As in the Milgram experiment and other social psychology experiments on conformist behavior, the potential inductee, in the absence of disagreement, is likely to change his opinions. And, as we have seen, because of the self-selection process, there is unlikely to be strong disagreement among the workshop attendees. Galanter's study of eight workshop sequences reveals this gradual attrition

according to commitment. Of the 104 guests at the initial 2-day workshops, 74 did not continue. Of the 30 at the 7-day workshops, 12 did not continue (including a few who were rescued by their families, and a few who were told not to continue by the Church). Of the 18 remaining at the 21-day workshops, 9 did not continue to membership. And of the remaining 9, 6 were active church members 6 months later.

The example of the Moonies illustrates a process of conversion. Converts make a sequence of small decisions to accept authority. Ultimately, as a result of this sequence of decisions to obey rather than to rebel, the converts develop beliefs and values very different from what they had at the beginning of the process. This willingness to acquiesce to authority is abetted by self-selection. Those who agree most with the Church self-select into the group. Because those who disagree most exit, the dissent necessary for resistance to escalation of commitment does not develop.

B. Synanon

The case of Synanon is possibly the best studied, as well as being, in the end, one of the most horrific of these cult groups. In this group we can see the pressure for obedience to authority operative in the Milgram experiment, as well as the selective exit of would-be dissenters who could break the isolation necessary to maintain this obedience to authority.

Synanon was initially an organization devoted to the cure of drug addicts, but it gradually evolved into a paramilitary organization carrying out the increasingly maniacal whims of its founder and leader. (My account comes from David Gerstel, 1982.) The leader, Charles Dederich, as well as the other founders of Synanon, adapted the methods of Alcoholics Anonymous for the treatment of drug addiction. At the time, little was known about drug abuse in this country; it was also widely believed that drug addiction was incurable. By proving the contrary, Synanon received considerable favorable publicity. With aggressive solicitation of gifts (especially of in-kind tax deductible gifts) and commercial endeavors

such as the sale of pens, pencils, and briefcases with the Synanon logo, it expanded from a houseful of ex-addicts, first to a large residential site in Santa Monica, and, at its peak, to several residential communities in both northern and southern California with more than 1,600 residents (Richard Ofshe, 1980, p. 112).

To understand the path of Synanon from these benign origins into what it eventually became, it is necessary to focus on the methods of control in the organization. The members led dual lives: daytime workday lives, and nighttime lives spent in a pastime called *The Game*. The daytime lives of members were devoted to hard work, especially for the cause of the community. Members were given virtually no private property and were expected to donate their own resources to Synanon; they had virtually no privacy. Gerstel reports his first impressions of Synanon as amazement at the cleanliness of the buildings, the orderliness of the grounds, and the cheerfulness of the workers. The daytime code of Synanon was to maintain a cheerful positive attitude at all times, exemplified by the song of the trashmen: "We're your Synanon garbage men./ We don't work for money. Ooooh, we don't work for cash./ We work for the pleasure/ Of taking out yo' trash" (Gerstel, p. 5).

At night, however, the unbridled positivism was given up, and members acted out their hostility and aggressions in *The Game* (adapted from the practices of Alcoholics Anonymous, from which Synanon originated). Participants in the game were expected to be brutally frank in criticizing any other member who did not live up to the standards expected of Synanon. Because the lives of the members were so open to each other, these criticisms could extend to the smallest detail. Since members had virtually no privacy, this criticism naturally monitored any deviation from the purposes of the organization. The incentives of *The Game* induced members to strive to maintain the very best behavior.

The Game, however, like any other game, had rules, and those rules led to complete control of this fairly large community by its leader. These rules encouraged the criticism of members by one another, but forbade

criticism of the goals of Synanon itself or any shortcomings of its leader. Anyone who criticized the organization or its leadership would be harshly criticized by all (an incentive not to engage in such activity). If that criticism persisted, the offender would be banished from the community.

Under these rules of behavior, Synanon evolved into an organization under the control of a leader who became increasingly insane. In the late 1970's, Dederich insisted that members follow his every whim that included, to give some examples, enforced dieting (the Fatathon), enforced vasectomies for all males, and an enforced change of partners, first of all for married members of the community, and subsequently for all paired members whether married or not. Those who did not go along with these measures were "gamed," that is, criticized vehemently in *The Game*, beaten up, or evicted. During this period, Dederich was also building up his own armed paramilitary force that reacted against threats both within and outside the community. Within Synanon, dissenters were beaten up. Outside, passersby or neighbors with real or presumed insults aimed at the community were accosted and beaten, often severely. One former member, who was suing for the custody of his child still living there, was beaten to the point of paralysis, never to recover. Dederich was eventually convicted on a charge of conspiracy for murder—for sending unwanted mail to a Los Angeles attorney who was fighting Synanon: two Synanon vigilantes were found leaving a poisonous rattlesnake in his mail box.

The Synanon experience follows closely what Milgram observed in the laboratory. At each move by Dederich, the members were forced individually to decide whether to obey or to disobey. Disobedience involved the present cost of leaving the group and seeking immediately a new way of life with insufficient human and financial resources. Many members in the past had found life outside Synanon painful and had sought refuge there. Thus the consequences of disobedience were immediate and salient. As members chose the course of obedience, their norms of behavior as members of Synanon gradually changed, just as the

norms of behavior of Milgram's subjects changed according to the level of punishment they had previously administered. The process was aided, in Synanon as in Milgram's laboratory, by the absence of dissent. In Synanon the absence of dissent was ensured in usual circumstances by *The Game* and in unusual circumstances by forced expulsions.

VI. Crime and Drugs

Economists modeling crime (see Becker, 1968) and drug addiction have viewed the decisions to engage in these activities as individually motivated. Becker and Murphy, following Stigler-Becker, have even viewed the decision to pursue addictive activities as both rational and forward looking. The Milgram experiment and the behavior of cult groups, if nothing else, serve as warnings. It is inconceivable that the participants in Milgram's experiment were forward looking. These participants could not imagine that anyone (least of all themselves) would behave as they ultimately did. Likewise, the flower children of Synanon of the 1960's could not have conceived of themselves turning into gun-toting toughs in the 1970's. The assumption of forward-looking rationality regarding the change in their consumption capital, to use Stigler-Becker terminology, is totally violated.

The analogy between cult groups and the behavior of teenage gangs, where most criminal activity and drug addiction begin, is fairly complete. A member of a teenage gang typically finds himself (much less frequently herself) in a position very similar to that of a member of Synanon. The typical member of a gang makes a sequence of decisions that results in an escalating obedience to the gang leadership. At each stage of his career as a gang member, he makes the choice whether to obey or to disobey. In extreme cases, disobedience leads to expulsion from the gang. The gang member thus faces the same dilemma as the member of Synanon: whether to forsake friends who are close and in an important respect define his way of life, or to go along with the gang decision. In rising from junior to senior membership in the gang, or in following a

leader who himself is becoming deviant, the gang member by obeying increases his commitment to obedience. The situation is exactly analogous to that of subjects in the Milgram experiment.

Furthermore, the isolation from dissent obtained in Milgram's laboratory also naturally occurs in teenage gangs. The major activity of such gangs, according to David Matza (1964) is hanging out, and the major activity while hanging out is insulting other gang members to see how they respond. This activity is called "sounding," because it measures the depths of the other member on his response to the insult. The depth probe usually focuses on the manliness of the gang member and/or his commitment to the gang itself. The probing of his commitment to the gang plays the same control function as *The Game* in Synanon. Those who display less than full commitment to the gang in sounding, or to Synanon in *The Game*, suffer a form of public censure. Such procedures make members reluctant to voice their disagreements with the goals or activities of the gang, just as members of Synanon found it difficult to display negative attitudes toward the group. Thus members of teenage gangs find themselves in isolated positions, unable to resist the aims of powerful and deviant leaders. The ethnographies we have of such gangs support the importance of sounding and the role of important leaders who play a disproportionate role in planning gang activities (see Jay MacLeod, 1988, and William Whyte, 1943).

Just as the participants in the Milgram experiment "drifted" into obedience, and members of Synanon drifted into gangsterism, Matza (1964) showed how teenagers "drift" into delinquency. Matza (1969) likens the process of becoming delinquent to "religious conversion." The analogies of *drift* and *conversion* are both consistent with my model of time-inconsistent behavior. Like the cult groups I have just described, delinquent teenage gangs have mechanisms that work to preserve their isolation from outside influences. Should we be surprised that many such gangs with few social constraints engage in harmful deviant activity?

Consider the activities, as chronicled by MacLeod, of the "Hallway Hangers," a gang

who live in a low-income housing project in a New England city. The major activity of this gang is hanging out in Hallway #13 and sounding each other, with varying degrees of playfulness and malice. While hanging out, the gang ingests a wide variety of stimulants, including beer in vast amounts, a great deal of marijuana, some cocaine, PCP, and mescaline, and occasionally some heroin. The central value of this group is its loyalty to the gang and the other members, just as Synanon's central value from its inception to its end was the loyalty of members to the general community. The ethos of this gang is illustrated by MacLeod's story of Shorty and Slick, when they were caught ripping off the local sneakers factory (as told by Shorty):

See, that's how Slick was that day we were ripping off the sneakers. He figured that if he left me that would be rude, y'know. If he just let me get busted by myself and he knew I had a lot of [...] on my head, that's what I call a brother. He could've. I could've pushed him right through that fence, and he coulda been *gone*. But no, he waited for me, and we both got arrested. I was stuck. My belly couldn't get through the [...] hole in the fence.

[pp. 32-33]

This same aspect of gang behavior was emphasized 50 years ago in the classic street corner ethnography by Whyte. He explained the lack of social mobility of the most capable corner boys by their unwillingness to adopt a life style that would have sacrificed friendships with peers who would not advance with them. Just as Slick did not run when Shorty got caught in the fence in MacLeod's account, the leader of the "corner boys" Doc, in Whyte's account, fails to advance himself in school so he can remain with his friends.

Such gangs provide a perfect social environment for regrettable decisions. Gang members find the costs of nonacquiescence especially salient, since such nonacquiescence leads to isolation from the social group to which they are committed. As occurred at Synanon in a similar environment, gang members can then be led step-by-step

to escalating levels of crime, drugs, and violence, with each preceding step setting the norm for the next.

The question remains how to alter such behavior by social policy. William Wilson (1987) has argued the importance of the move from the central city to the suburbs of the middle class, which, he says, has resulted in the disappearance of social networks that formerly were the pathways to employment. According to Wilson, the result, especially in the black community, has been a dearth of employed (and therefore eligible) males and a dramatic increase in out-of-wedlock births.

There is, however, another effect of the disappearance of the urban middle class for poor youth left in the central cities. This disappearance has left fewer alternative social groups for those who do not want to acquiesce in the violent acts of their peers, thus making such acquiescence and gang violence more frequent.

Social policy should have the role of recreating, artificially if necessary, the beneficial social networks that have vanished. This would reduce the cost of dissent by gang members to criminal, violent, or drug-prone actions by providing alternatives. In addition, we have seen that just a little bit of dissent, and therefore perhaps just a little bit of information, may stop escalation toward commitment. Lisbeth Schorr (1989) has compiled a long list of social projects that have significantly reduced the problems of the underclass, problems such as teenage pregnancy, school truancy, drug abuse, violence, and alcoholism. In each of these projects, the key to success has been the special effort by social workers involved to gain the trust of their clients. The success of these projects shows that, when isolation can be broken and trust established, small amounts of information can significantly reduce the number of regrettable decisions.¹⁰

Evidence for the view that social isolation results in high crime rates comes from the

positive correlation between crime rates and city size. Smaller cities have less room for specialization in social groups than larger cities—so that isolation from common social norms is more difficult to attain. They also have lower crime rates. Cities with less than 10,000 people have one-fifth the violent crime rates of cities with populations more than 250,000. In 1985, cities with over 250,000 people had 50 percent higher violent crime rates than those cities with populations between 100,000 and 250,000 (U.S. Bureau of the Census, 1987, p. 157).¹¹

VII. Politics and Economics

Economists who have applied the tools of their trade to the political process have studied the workings of democracy and majority rule under individualistic values (see Kenneth Arrow, 1963). They are optimists. The model of cult group behavior, in contrast, is relevant in understanding politics' darker side. I will give two illustrations.

A. *Stalin's Takeover*

My first example concerns Stalin's ascension to power in Russia. The history of the Bolshevik party and the history of Synanon are strikingly similar. (I take the Bolshevik history from Isaac Deutscher, 1949). Initially, there were the early days of reformist zeal, of meeting secretly in lofts, warehouses, and other strange places. But, in addition, and most importantly, there was commitment to the organization. To the Bolsheviks, this commitment was of paramount importance. Indeed, it was over the constitutional issue as to whether party members should merely be contributors (either financial or political) or should, in addition, submit to party discipline that split the Russian socialist workers' movement into two parts—the Mensheviks and the Bolsheviks. This loyalty to party discipline, useful in the revolution, ultimately enabled

¹⁰In the case of the Unification Church, such active intervention frequently occurred as members were captured by relatives and forcibly deprogrammed (Galanter, 1989).

¹¹Some of these differences undoubtedly are due to the concentrations of poor people with high crime rates in central cities that are large in size.

Stalin to take over the party and pervert its ideals. It underlay the acquiescence of his tough comrade revolutionaries in the scrapping of the original principles of Bolshevism: open intraparty debate and dedication to the cause of the workers and peasants. In the 1920's and 1930's, as Stalin collectivized the peasants and tyrannized over dissidents, these old comrades stood by, perhaps not quite agreeing, but not actively disagreeing either, much like Milgram's passively obedient, passively resistant subjects. Even Trotsky in exile did not unambiguously oppose Stalin until the purges had begun as a series of decisions were made that increasingly brutalized the peasantry and cut off political debate. The exception to the lack of dissent proves the rule. Nadia Alliluyeva was the daughter of one of the founding Bolsheviks and thus an heiress by birth to the ideals of the party. She was also Stalin's wife. When Stalin collectivized the peasantry, moving perhaps 80 million from their farms in six months' time, she voiced her disapproval at a party—he replied savagely. That night she committed suicide.¹² This behavior contrasts with the party leadership who, like Milgram's subjects, had been participating in the decisions that were being taken. At each juncture, they were confronted by the decision whether to break ranks with the increasing brutalization of the peasants and the choking off of dissent, or to remain loyal to the party. By acquiescing step by step to the crescendo of Stalin's actions, they were committing themselves to altered standards of behavior. In contrast, Nadia Alliluyeva, who had withdrawn from the decision-making process to be wife and mother, could feel proper revulsion at the deviation of the party's actions from its prior ideals.

B. Vietnam War

A second example of the type of deviant group process I have described occurred in President Johnson's Tuesday lunch group,

which was the executive body controlling U.S. military decisions in the Vietnam War (Irving Janis, 1972). Here we see all of the features characterizing our model of salience, authority, and obedience. First, there was the gradual escalation of violence against the Vietnamese. Bill Moyers, reflecting on Vietnam policy after he was out of office, precisely describes how this escalation of commitment happened: "With but rare exceptions we always seemed to be calculating the short-term consequences of each alternative at every step of the [policymaking] process, but not the long-range consequences. And with each succeeding short-range consequence we became more deeply a prisoner of the process" (Janis, p. 103). The subjects in Milgram's experiments could have said exactly the same thing.

The control of dissension within President Johnson's Tuesday lunch group bore close resemblance to the processes at work in Synanon and the Hallway Hangers. The president would greet Moyers as "Mr. Stop-the-Bombing"; similar epithets were applied to other dissenters within the group: "our favorite dove," "the inhouse devil's advocate on Vietnam" (Janis, p. 120). A teenage gang would probably consider these soundings mediocre, but their lack of style may not have affected their impact. And the measures within the group which were taken to enforce unanimity ("groupthink" according to Janis) were supplemented by more or less voluntary exit as dissenters at different times came to disagree with the policy: Bill Moyers, George Ball, McGeorge Bundy, and Robert McNamara. Interestingly, since each of these individuals exited fairly soon after they developed deep reservations about the policy, there was active dissent for only a small fraction of the history of the group.

VIII. Bureaucracies

My examples of obedience to authority, so far, have centered primarily on noneconomic phenomena: religion, crime, drugs, and politics. However, the phenomenon of obedience to authority is also prevalent in bureaucracies that in a modern industrial-

¹²An alternative account of Alliluyeva's decision to commit suicide and Stalin's activities on the night before is given by Nikita Khrushchev (1990). The two accounts are not mutually exclusive.

ized society, are the sites of most economic activity.

One function of bureaucracies, following Robert Merton (1968, p. 250) and Weber, is to create specialists. A second function of bureaucracies is "infusing group participants with appropriate attitudes and sentiments" (Merton, 1968, p. 253). We could interpret the Milgram experiment as a toy bureaucracy, and my model of that experiment as a model of that bureaucracy. In that case, W_{t-1} , the level of voltage that a subject has grown accustomed to giving, constitutes his "attitudes and sentiments." In Merton's terms, it defines his bureaucratic personality.

The specialization mentioned earlier can result in bureaucratic personalities that are "dysfunctional," to use Merton's terminology. We have already seen such dysfunction in the behavior of the Moonies, Synanon, teenage gangs, drug and alcohol abusers, the Bolshevik party, and President Johnson's Tuesday lunch group. The changes that occurred in individual decision-making behavior were "latent," to use another of Merton's terms, since they were not understood by the participants and were unintentional. Furthermore, these changes occur exactly as I have been picturing: in making a sequence of small decisions, the decision maker's criteria for decisions gradually change, with preceding decisions being the precedent for further decisions. Merton gives an example of the consequences of such bureaucratically engendered personalities in the U.S. Bureau of Naturalization concerning the treatment of the request for citizenship of Admiral Byrd's pilot over the South Pole.

According to a ruling of the Department of Labor Bernt Balchen... cannot receive his citizenship papers. Balchen, a native of Norway, declared his intention in 1927. It is held that he has failed to meet the condition of five years' continuous residence in the United States. The Byrd antarctic voyage took him out of the country, although he was on a ship carrying the American flag, was an invaluable member of the American expedition, and in a region to which there is an American claim because of the explo-

ration and occupation of it by Americans, this region being called Little America.

The Bureau of Naturalization explains that it cannot proceed on the assumption that Little America is American soil. That would be trespass on international questions where it has no sanction. So far as the bureau is concerned, Balchen was out of the country and technically has not complied with the law of naturalization. [p. 254, quoted from *The Chicago Tribune*, June 24, 1931, p. 10]

Popular proponents of bureaucratic reform (for example, William Ouchi, 1981, and Thomas Peters and Robert Waterman, 1982) have emphasized the benefits of non-specialization within firms precisely because they recognize that nonspecialists have a wider range of experience than specialists and thus are less likely to have developed special bureaucratic personalities. Also, as consistent with my secondary theme in earlier examples, nonspecialists by nature are less isolated than specialists. The use of nonspecialists may break the isolation necessary for the development of dysfunctional bureaucratic personalities.

Economic models of bureaucracy have typically been based on principal-agent theory. Their purpose is to derive optimal organizational structures, contingent on the technical nature of information flows. (Two excellent examples are Paul Milgrom and John Roberts, 1988, and Bengt Holmstrom and Jean Tirole, 1988). In contrast, my analysis suggests an alternative way in which information affects the performance of a bureaucracy. Bureaucratic structures that make specialized decisions may behave in "deviant" ways. In special cases such as dedicated scientists in the laboratory, the Green Berets, or the U.S. Forestry Service (see Herbert Kaufman, 1960), this isolation may be beneficial and the deviance quite functional.¹³ On the other hand, as we have

¹³In the case of scientists, it may not just be individual but also group psychology under isolation that results in the odd scientific personalities exemplified by the "mad scientist" image.

seen, this same specialization may be dysfunctional. Entirely absent from the principal-agent model is the possibility that behavior changes occur latently in response to obedience to authority. While the theory of bureaucracy must address incentive problems (as in principal-agent problems), it should also consider the need to organize decision making so as to create functional (rather than dysfunctional) changes in personalities.

IX. Conclusion

Standard economic analysis is based upon the Benthamite view that individuals have fixed utilities which do not change. Stigler-Becker and Becker-Murphy have gone so far as to posit that these utilities do change, but that individuals are forward looking and thus foresee the changes that will occur. A more modern view of behavior, based on twentieth-century anthropology, psychology, and sociology is that individuals have utilities that do change and, in addition, they fail fully to foresee those changes or even recognize that they have occurred. This lecture has modeled such behavior in sequences of decisions, given examples from everyday life, indicated the situations in which such behavior is likely to occur, and, in some instances, suggested possible remedies. The theory of procrastination and obedience has applications to savings, crime, substance abuse, politics, and bureaucratic organizations.

The Economics Major: Can and Should We Do Better than a B—?

By JOHN J. SIEGFRIED, ROBIN L. BARTLETT, W. LEE HANSEN,
ALLEN C. KELLEY, DONALD N. MCCLOSKEY,
AND THOMAS H. TIETENBERG*

Yes, and yes.

The two questions asked in the title of this paper were prompted by an invitation to the American Economic Association's Committee on Economic Education to participate with eleven other disciplines in a national review of arts and sciences majors initiated by the Association of American Colleges (AAC). The goal of this "Project on Study-in-Depth" was to evaluate the economics major within the liberal arts curriculum, highlighting connections and interactions among disciplines. In the process we examined the economics major in considerable detail. The result was a lengthy report,¹ from which the present paper abstracts key findings, focusing on the purpose of the major, recommendations for improvement, and methods for effecting change.

In compiling the AAC report we became painfully aware that while our collective experience in the field of "economics education" provides us with considerable background, the representativeness of our

judgments required checking. To this end, seminars were given at several colleges and universities and over 100 copies of the report were circulated to other economists, including leading economic educators; feedback was incorporated in subsequent versions. In addition, in May 1990 a survey of economics faculty at 127 colleges and universities was undertaken with the goal of vetting and evaluating our main conclusions and recommendations.

As a part of that survey, respondents were invited to complete a "report card" (A,...,F) based on twelve criteria evaluating the effectiveness of the economics major at their institutions.² Tabulated on a 4.0 grading scale, the economics major earned an overall grade of B—. An analysis of the detailed statistical tabulations and open-ended responses to some thirty-seven questions suggested how it might be improved.

In this paper we argue that the quality of the major is suboptimal, a situation probably resulting from two decades of expanding enrollments and the relative popularity of the major, which occurred just when demands on faculty for research and other responsibilities greatly increased, and when college administrations tightened con-

¹The Economics Major in American Higher Education," *Journal of Economic Education*, No. 3, Summer 1991, 22. The present paper defers to that article for all literature references.

²The criteria included aspects of course content, the institutional environment (for example, manageability of class size, effectiveness of instructional methods, adaptation to student learning styles, connections with other courses in economics), and skills developed (analytical, mathematical, empirical, critical judgment, applications, oral/written communication, ability to think like an economist). A copy of the questionnaire, list of participating schools, and survey results is available from the Joint Council on Economic Education, 432 Park Avenue South, New York, 10016.

straints on faculty size in preparation for expected declines in enrollments in the 1980's. This stocktaking indicates that the economics major merits improvement. Here we provide specific suggestions to accomplish that objective.

I. The Goal of the Major

Enabling students to develop a capacity to "think like an economist" is the overarching goal of the major. All other virtues follow. Thinking like an economist involves using chains of deductive reasoning in conjunction with simplified models (such as supply and demand, benefit-cost analysis, and comparative advantage) to illuminate economic phenomena. To some, economists tend to abstract too much from the richness of human behavior and reality; to many economists, the strength of our analysis is the provision of focus and clarity of thought; parsimonious models are a virtue, not a vice.

Thinking like an economist also involves identifying and evaluating tradeoffs in the context of constraints, distinguishing positive from normative analysis, and tracing behavioral implications of change while abstracting from aspects of reality. It, moreover, involves describing redistributive implications of change, amassing data to evaluate economic events, and testing hypotheses about how consumers and producers make choices and how the economy works. Finally, thinking like an economist involves examining many problems through a filter of efficiency—coping with limited resources.

Thinking like an economist requires creative skills, too. Identifying economic issues and problems, framing them in ways other people do not see, devising novel policy proposals for dealing with problems, analyzing both the intended and unintended effects of policies, and devising innovative methods to estimate the magnitude of these effects—all are as central to the discipline as is the development of logically coherent theories.

This statement of purpose appeals to the vast majority of economics faculty in American colleges and universities. But how can

we be assured that our undergraduate students really meet this objective by the time they walk across the graduation platform? Here we present a blueprint for reform of the economics curriculum which we believe will help students better understand how to think like an economist.

II. Recommendations for Improving the Major

An ideal program for the major includes *foundation requirements* (introductory macro and micro, intermediate macro and micro theory, and quantitative methods), a *breadth requirement* (elective courses), a *depth dimension* which probes more deeply the structure of knowledge in elective courses, and a *capstone experience*, whereby students apply their knowledge and skills in creative and systematic ways through research and writing.

We believe substantial opportunity exists for improving each component of the curriculum. In this section we identify areas of deficiency and make recommendations for change.

A. Foundations I: The Introductory Courses

Introductory courses expose students to economic theory, principles, and concepts, and instruct them how to apply the economists' tools to analyze problems and unfamiliar situations. These courses typically serve both economics and business majors and students attempting to satisfy the institution's general education requirements.

Deficiencies. Introductory courses tend to be encyclopedic, and all too often oriented toward formalism of theory at the expense of application.

Recommendation.

1) Emphasize the *application* of a limited number of important concepts and theoretical tools to a variety of problems, at the expense of some of the existing formal and detailed elaboration of theoretical constructs or the extent of coverage of the vast array of topics contained in most textbooks.

Our survey indicates that this orientation and recommendation commands considerable support. In fact, it represents the dominant approach of most existing intro-

ductory economics courses. Fortunately, these courses constitute a relatively sound component of the major at most colleges and universities.

B. *Foundations II: The Intermediate Theory Courses*

Intermediate theory courses accomplish three goals. First, they show how economists develop and use theory, and how rigorous thinking illuminates economic phenomena. Second, they provide prerequisite tools required to undertake economic analyses in elective courses. Third, they provide important information or signals to students: what the major is like, what content must be mastered, what skills must be developed, and what standards of performance must be met.

Deficiencies. While most intermediate macro and micro theory courses develop well the rigor and elegance of economic theory, they tend to slight a critically important issue: how theory and real world events interact to produce new knowledge, concepts and theories, and how such theories are evaluated. In particular, the "usefulness" of theoretical topics and paradigms, largely evaluated by confronting theory with data; applying models to various problems, and comparing the outcomes of alternative theoretical constructs, merits greater emphasis.

Recommendations.

- 1) Coordinate content so that these courses establish a foundation of knowledge and skills on which other courses and instructors can rely.
- 2) Establish explicit connections between theory and its empirical counterparts, to help students appraise the importance of theoretical constructs, to provide a basis for selecting assumptions, and to show that theory is relevant.

Again, students are reasonably well served by these courses, although our second recommendation merits emphasis. Use and appraisal of theory should in practice constitute the primary basis for establishing the course "standard"—the level of difficulty, as it were, for screening students interested

in the major. While facility with formal theoretical constructs should represent a necessary condition for passing these courses, it should not be sufficient. Students must, in addition, be able to *use and appraise* theory—a challenging, but arguably a central skill as a "gateway to the major."

C. *Foundations III: The Quantitative Methods Courses*

Quantitative methods courses expose students to the empirical dimensions of economics: the techniques for testing and evaluating our understanding of economic phenomena and economic behavior. These courses usually emphasize algebraic skills and statistical techniques.

Deficiencies. The dominant attention to the formal aspects of statistical analysis shortchanges students' exposure to how these methods are applied in the empirical work economists do, and to the criteria for and methods of selecting and appraising the data used in empirical analysis.

Recommendations.

- 1) Reorient the course from its almost singular statistical orientation to emphasize a wider range of quantitative methods pertinent to economic analysis.
- 2) Increase the allocation of time to the most widely used (but still accessible) methods employed by economists in their empirical research.
- 3) Devote more attention to limitations imposed by the absence of appropriate data, poor quality of existing data, and use of proxy variables; illustrate creative attempts to overcome these difficulties.

We propose a broader quantitative methods course, one that devotes more attention to research design and to the context within which quantitative methods are applied. The former requires giving students a better sense of what is involved in research—from formulating the underlying question to conceptualizing the study and organizing the process for completing it. The latter requires knowing something about measuring economic behavior and phenomena; selecting, organizing, appraising, and manipulating economic data; having the ability to test

hypotheses; and knowing how to interpret the results of various statistical procedures.

D. Breadth

Breadth is typically achieved by students self-selecting elective courses to explore subfields and topics within economics, which draw upon the foundation courses, and are often enriched by historical, institutional, and empirical detail. As few as three, and as many as six or seven courses are taken, and the choice is usually unconstrained.

Deficiencies. This format all too often results in students acquiring a narrow, parochial perspective, unable to come to grips with deviations from marginalist thinking, and incapable of dealing sensibly with problems that involve approaches different from atomistic models of individual choice.

Recommendations.

Require at least four or five elective courses.

Structure student choices to produce greater breadth: we recommend at least one course each in 1) contextual, 2) international, and 3) public sector economics.

Contextual inquiry includes courses in economic history (where connections between economics and history are explicit), history of economic thought (where different modes of thought are exposed), comparative economic systems (where social/political/cultural dimensions that influence distinctive economic systems are compared), and area studies (where synthetic analyses of countries and regions are explored). Such courses take the edge off narrow thinking about economics, and they illuminate the importance of context and structure (initial conditions and constraints) that shape the dominant "marginalist" orientation of economics.

International courses include not only traditional offerings in trade and finance, but also those in economic development, comparative systems, and traditional fields that may incorporate a notable international component (for example, the multinational corporation). Such courses expand students' perspective from the parochial to the global, placing them in a stronger posi-

tion to use their tools of economic inquiry in a world that is rapidly becoming more integrated.

Public sector economics courses include not only the usual ones in public finance and taxation, but also some offerings in theory (stressing public goods, externalities, collective decision making, and market failure), labor economics (stressing aspects of labor regulation), and the like. Such courses simultaneously illuminate and qualify the role of individual, free market choice, a dominant paradigm in economics. Students should gain considerable understanding of the applicability, methods, and limitations of collective choice, including nonmarket options for resource allocation. These dimensions of decision making account for one-third to almost all resource allocations in most countries, and they are too important to relegate to a few weeks of exploration in the foundation courses.

Feedback from our survey about the breadth recommendations was strongly positive, although some respondents expressed legitimate concern about the administrative feasibility of offering enough courses on an annual basis to provide such breadth. This concern can be addressed by defining the breadth options in ways that are consistent with the capacity of institutions to staff such courses.

E. Depth

Depth in elective courses is accomplished by going beyond the coverage of textbook-oriented field courses to how current knowledge evolved and how new knowledge is developed in the field.

Deficiencies. While students often leave elective courses with sound "state of the art" surveys of coverage, they often lack a feeling for the field's central research issues, how knowledge about them has developed over time, and how the ideas revealed in the courses are related to the fundamental theories of economics.

Recommendations.

1) Link the important ideas in elective courses to general principles introduced in the theory courses; at least some of the

elective courses should require an intermediate theory course as a prerequisite.

2) Examine how economic phenomena and behavior are observed and measured, pertinent empirical data are appraised and selected to illuminate these phenomena, and how these data can be effectively organized and analyzed.

3) Explore the process of expanding existing knowledge and developing new knowledge in the field.

F. Capstone Experience

A capstone experience can help complete the process of intellectual maturation. Such an experience is achieved by giving students opportunities to apply what they have learned to an economic question or problem—in effect, “doing economics.” In the process they acquire an increased capacity to “think like an economist.” Completion of such an experience is typically accomplished by writing a senior thesis, carrying out an honors research project, or enrolling in an independent study course. In some institutions, special senior seminars facilitate these opportunities.

Deficiency. Too few institutions offer these opportunities.

Recommendation.

1) Provide more opportunities for advanced students (seniors) to “do economics” by undertaking a substantial independent project that requires majors to formulate an underlying question or problem, to structure an analysis, to assemble the information necessary to carry out the analysis, to draw conclusions from the results, and to communicate the findings to others in both oral and written form.

While such a capstone experience is educationally sound for all majors, in practice departmental resources may be constrained. When constraints prevent extending this opportunity to all majors, such courses are most productively offered to more capable students, often in an honors program.

III. Getting It Done

A respectable economics major that teaches students how to think like an

economist requires considerable instructional resources, especially if, as we argue, students must obtain extensive practice at really *doing* economics. To be successful, this requires relatively small classes, 20–25 students in intermediate macro and micro and elective courses, and approximately 15 students in courses emphasizing writing, oral presentations and argumentation, and research projects.

Deans and chairs will immediately observe that such a major is expensive, and thus “compromises” must be made. Counterarguments are that economics carries more than its share of costs with its large introductory courses; indeed, its cost per credit hour is likely to be lower than those of many other departments and much lower than those of many science courses with their laboratory and discussion sections. More important, the low-cost technology of large classes, the lecture format, and multiple-choice examinations (so prevalent throughout the economics curriculum) have often resulted in majors simply being “exposed” to economics in varying degrees. Lamentably, in all too many instances, even the *minimum* mastery level of understanding how to think like an economist is sacrificed.

When the production of minimally acceptable output requires a much higher-cost technology, how is it possible to make the major work? The answer, it seems to us, is simple: either increase faculty or ration access to the major to fit the resources available while maintaining quality standards and fulfilling the responsibilities of each college or university. Placing a limit on the number of economics majors will conflict with the “philosophy” of many institutions. However, surely unconstrained access to the major without concomitant resources, resulting in diminished standards that compromise the intellectual integrity of the enterprise, is also at variance with prevailing educational philosophy. Responsible educational planning requires “living within one’s budget” of instructional resources. Thus, the question of *how* to ration access to the major becomes paramount.

The method of rationing may vary from school to school, depending on the institu-

tion's policies and procedures. Whatever method is used, however, it should be *educationally sound* with respect to the *goals* of the major. Our own preference is to offer intellectually challenging intermediate micro and macro and quantitative methods courses whose "reputation" ensures that the number of students intending to major does not exceed capacity.

What does and does not constitute "intellectual challenge" in such courses must be spelled out. It does *not* require the use of formal (and seemingly difficult or sophisticated) tools (mainly mathematics); and it does *not* involve the use of unfair or tough grading standards, unreasonable assignments, or "scare tactics" as techniques to discourage enrollments. It *does* require holding students to the standard of properly *applying* reasonably sophisticated economic ideas to a variety of unfamiliar problems. This standard is intellectually more demanding than facility with formal tools per se, and it is, in fact, the best early indicator of whether a student has the ability to come to grips with the major. (Parenthetically, introductory courses should *not* be used to ration access to the major since such courses should be widely

accessible to nonmajors and students of diverse backgrounds and goals.)

As a result, students should be in classes sufficiently small to permit them to interact effectively within their instructors. Professors should then be expected to employ evaluation methods that give students an opportunity to develop and use writing and oral skills. Learning should take a more active form, and therefore have longer lasting effects.

The undergraduate economics major has slipped in quality over the past two decades as large enrollments undermined standards. We see no reason why large *enrollments* in economics programs need pose a problem. Indeed, offering exceptionally high-quality introductory economics courses (even if taught in large classes) should be a primary goal of economics departments. A related goal is to ensure that economics is one of the most exciting and intellectually challenging majors. Having said all this, we believe the central task is to make certain that economics majors understand how to "think like an economist"—surely a highly demanding but attainable goal. To accomplish this, tough choices—the hallmark of economics—must be made.

An Agenda for Research on Economic Education in Colleges and Universities

By WILLIAM BECKER, ROBERT HIGHSMITH, PETER KENNEDY,
AND WILLIAM WALSTAD*

The quantity of research on economic education at the college and university level declined during the past decade. In the 1980-90 period, the number of research-related articles on economics instruction in higher education fell by about 17 percent from the number published during the 1969-79 period. A possible reason for this reduction may have been the publication of a review of research on economic education at the college and university level by John Siegfried and Rendigs Fels (1979). This extensive survey may have inadvertently led researchers to believe that most of the major topics at this level had been studied and that further research would not yield insights. Another reason could have been the success of the Joint Council on Economic Education in directing resources to precollege issues.

Whatever the reasons for the college-level decline, it is disturbing because we think the teaching of economics in colleges and universities can be improved by research on what influences the delivery and the effectiveness of instruction. In our view, research on economic education at the postsecondary level should be directed to three major areas. First, the multiple outputs from learning economics need to be defined, measured, and investigated so that a fuller range of benefits from studying economics can be incorporated into decisions about courses and degree programs. Second, more emphasis should be placed on the analysis

of the economics major, as distinct from individual courses, to enhance the structuring of programs. Third, the replication of earlier research is required to determine the extent to which conclusions drawn from those studies still hold and to relate those findings to new developments.

I. Multiple Outputs

College economics courses may contribute more to student development than can be measured by scores on a cognitive test. W. Lee Hansen (1986), for example, described five "proficiencies" that he thinks students should be able to demonstrate from majoring in economics (i.e., gaining access to existing knowledge, displaying command of existing knowledge, displaying the ability to draw out existing knowledge, utilizing existing knowledge to explore issues, and creating new knowledge). This demonstration would be difficult in a multiple-choice testing framework.

Recognition of the multiple outputs from studying economics has not gone unnoticed in the research literature in economic education. Hansen, Allen Kelley, and Burton Weisbrod (1970) discussed the need for more research on how desired outcomes and how the distribution of benefits from teaching differ among students. Judith Yates (1978) complained that our research horizons were too narrow because of our focus on easily measured outputs. Eric Hanushek (1979; 1986) described the importance of joint products in the educational process, and, in particular, faulted researchers in economic education for their singular emphasis on multiple-choice tests. Despite the widespread knowledge that there are multiple outputs from teaching, few studies in economic education have incorporated this fact.

*Indiana University, Bloomington, IN 47405; Joint Council on Economic Education, New York, NY 10016; Simon Fraser University, Burnaby, B.C. Canada V5A 1S6; and University of Nebraska, Lincoln, NE 68588-0402, respectively. This paper is an abridged version of a forthcoming *Journal of Economic Education* (Summer 1991) article. Constructive criticism on earlier drafts was provided by W. Lee Hansen, John Siegfried, and Michael Watts.

The problem of deciding how to value outcomes also must be considered. For example, William Becker, William Greene, and Sherwin Rosen (1990) argue against the use of change-score models in economic education research because these models ignore the fact that the market for new graduates does not place a value on student learning as much as it values the final level of accomplishment. They assert that the normative beliefs of an instructor or entire faculty about the importance of given intellectual skills is elusive without reference to what employers are paying for the bundle of skills embodied in the college graduate, and what they desire from the graduate. Becker and William Walstad (1990) also show that data loss from pretest to posttest may pose problems for assessing value added.

Debates on problems associated with the value added by education make clear that research on a wider coverage of outcomes from instruction will not be easy to conduct. Each output must first be clearly identified and accurately measured. A consensus also needs to be reached among researchers about what is required to assess each outcome. The scope of research work then must be broadened to include an array of outcomes, if they can be measured and are considered to be important.

Several research topics to be addressed in the context of multiple outputs seem to have particular relevance in considering inputs as well. First, what is the role of basic skills (i.e., reading, writing, computing, and mathematics) in economics courses? For example, do students who are asked to use mathematics in their courses gain a better understanding of economics than students who use limited mathematics? Conversely, does the study of economics significantly improve mathematics skills? It seems reasonable to think that basic mathematics skills are both an input for economics learning and an output from economics learning, but at present we have limited empirical data on these possible relationships. Better knowledge of the interaction between basic skills as inputs and outputs from economics instruction would be valuable for identifying prerequisites for courses.

A second subject for study is the relative merits of fixed-response (multiple choice) and constructed-response (essay or short answer) tests for measuring student achievement in economics. Although the shortcomings of fixed-response tests are well known, the benefits of reliable and valid measures of a multiple-choice-type test for evaluation and research may not be outweighed by the negatives. What is needed is further exploration of the relationship between student performance on fixed-response vs. constructed-response tests. Do the different tests capture different dimensions of student performance, or are they measuring essentially the same dimension? The value of fixed-response vs. constructed-response measures is debated among faculty members. There is a literature on the topic in other fields (see Hunter Breland et al., 1987), but the issue has not been thoroughly investigated in economics.

A third topic is research on learning retention. Research typically measures cognitive outcomes during an economics course. With the notable exception of Phillip Saunders (1980), no extensive research exists on the lasting effects from economics coursework because longitudinal data typically are not available. These data should be collected to investigate what students retain *X* years after completing coursework and a major in economics. Presumably there is a host of factors that explain retention from a course, a series of courses, or from the major. We also suspect that the level of retention differs across the multiple outputs.

A fourth area for research is the effect of instructors on student outcomes. The target for the work would be the identification of the attributes that exemplary teachers of economics develop as they accumulate more classroom experience; knowledge of the characteristics of good teaching should enable new instructors to shorten the time it takes to become better teachers. We also suspect that exemplary teachers, consciously or unconsciously, strongly affect more than one dimension of student development. A starting point for this research would be to survey economists who have won awards for

excellence in teaching. These findings could be compared to results from similar surveys in other disciplines, or to the extensive research on student evaluation of instruction in economics. Psychologists have also studied differences in the characteristics of "expert" and "novice" approaches to problem solving, and research of this type might have application to economics teaching.

II. The Economics Major

Although a few studies (for example, Siegfried and Jennie Raymond, 1984), have examined the economics major, more can be learned about the demand curve for course enrollments and majors. One question yet to be answered, for example, is why students take courses and/or major in economics. A related query is why students elect certain courses in economics when majoring in the subject. Factors such as course difficulty, instructor or department reputation, recommendations of peers, preparation for graduate school, or personal characteristics might be included in a list of factors influencing course selection or the decision to major in economics.

There are many alternative routes to a major in economics; for example, majors may have a business or social science orientation with emphasis on either applied or theoretical work. We need to know the benefits and drawbacks of these alternatives. In addition, the claim is often made that training in economics is central to an understanding of the complexities of the world. It is not clear to what extent this claim is justified relative to those of other social sciences or areas of study. How do economics majors evaluate their educational experience compared with students majoring in business or other social sciences?

Addressing these concerns will initially involve some survey work. The questions we are posing, however, are broader and focus on assessing the relative value of an education in economics as perceived by students who are taking classes or by those who have completed a course of study. Expansion of the data sources will be necessary for some of the evaluations. For example, alumni

records from colleges and universities might be exploited for examining the performance of students after graduation or for evaluating performance differences across alternative economics majors. Moreover, "successful persons" (top corporate executives, government officials, or community leaders) who have majored in economics could be contacted and asked how majoring in economics contributed to their success. Despite the potential for sample selection problems, a follow-up survey of alumni or the most successful alumni might identify features of economics that should be emphasized by departments.

III. Replications

Fundamental to sound research is the ability to replicate results. Economic education is sufficiently mature as a research area that some of the "accepted" results should be reexamined. Replication should not be mere duplication; it should also provide opportunities to extend previous work in new directions.

The questions that should be reexamined are numerous. One topic studied in the 1970's was how high school preparation in economics affects performance in the college principles of economics classes or the decision to select economics as a major (see Saunders, 1970). Since those studies were conducted, many changes have occurred in high school courses. A variety of "economics" courses are being mandated by states, and there is now an Advanced Placement course in economics (Stephen Buckles and John Morton, 1988). There are also more instructional materials available, and teachers may be better prepared to teach economics. These changes suggest that college students with experience in high school economics may have advantages that bear on their placement and treatment in college-level economics courses.

A second topic is the effects of class size. Although students tend to dislike large classes, many studies of introductory courses have found that class size has little influence on multiple-choice test scores once class size rises above a threshold level (David

Williams et al., 1985). Henry Raimondo, Louis Esposito, and Irving Gershenberg (1990), however, found that large classes at the intermediate level can be detrimental in some areas of economics. The work of David Card and Alan Krueger (1990) suggests that class size, as well as other expenditure variables, may affect the financial returns from education. The critical role of class size on the multiple outputs of economic education needs to be established.

A third topic, often debated in economics departments, is the optimum order in which courses are taken. For instance, does it matter if students take the microeconomics course before the macroeconomics course? Possibly because of differences in output measures and research design, studies by John Fizel and Jerry Johnson (1986) and James McCoy, David Brasfield, and Martin Milkman (1989) suggest conflicting answers to such questions. Related to these replications would be studies that address possible efficiency gains from condensing the two-semester principles courses into a one-semester course.

A fourth topic, controversial in many larger economics departments, is the increasing employment of graduate student instructors for whom English is a second language. Complaints have been raised by students, parents, and legislators about whether undergraduate students are able to perform as well with nonnative English-speaking instructors as they are able to do with native English-speaking instructors. Michael Watts and Gerald Lynch (1989) found that students with instructors for whom English was a second language performed less well than students with instructors for whom English was a first language. If this finding is supported by studies at other institutions, steps may be needed to upgrade the language and teaching skills of these potential instructors before they are permitted to teach.

A fifth topic is how student and instructor differences affect student outcomes and instructor performance. Studies have been done on the relationship between teaching style and learning styles. Replication of previous work and further study along these

lines may identify ways the teaching of economics can be structured to achieve a better match between the teaching styles of instructors and learning styles of students. Also, we need to know more about the role of gender, race, ethnic background, socioeconomic status, and general ability because they are likely to affect the multiple outcomes from economics instruction and related issues such as the decision to major in economics.

A sixth topic is the role of new technologies. In the 1960's, televised lectures were touted as a means to meet college enrollment demands. Mainframe computers were considered in the 1970's to add variety to classroom lectures and to manage instruction. The 1980's witnessed the introduction of the microcomputer and improvement in videotape technology. Yet few of these innovations got beyond the experimental stage. The applicability of research on past innovations to current innovations is of questionable value. We know little about the cost effectiveness of newer technologies on student performance in a course or in the major.

IV. Concluding Comments

We urge researchers in economic education to mobilize in this decade, as they did in the 1970's, to advance our understanding of the teaching of economics at the postsecondary level. The quality of work in economic education, at all levels, is steadily improving and researchers are finding more imaginative ways of addressing problems both old and new. Although by publishing this agenda we hope to influence the direction of future research in this area, we hope also that researchers will feel free to attack the problems they perceive to be important, in the ways they see fitting.

We recognize that some of our current agenda, in particular the part relating to multiple outputs, involves work requiring considerable resources and the coordination/interaction of several researchers. The AEA Committee on Economic Education (CEE) and the Joint Council on Economic Education (JCEE) must be encouraged to

develop a "social infrastructure" that allows individual researchers to tackle this agenda in an efficient manner. In this regard, we offer two final recommendations.

If multiple outputs are to play a prominent role in future research, individual researchers should be given guidance on what outputs are thought to be relevant, and how they are to be measured. We recommend that the JCEE, in cooperation with the CEE, solicit position papers on output measures from a range of scholars in a variety of disciplines, convene a conference to debate this issue, obtain a consensus on the outputs that should be used for assessment purposes, and develop instrumentation and data bases for these new output measures.

Much of the agenda overlaps extensively with research in education and in other disciplines. Economics is not the only discipline with an "education" division, and many learning concepts described in the education literature could provide fertile ground for research in economic education. Researchers in economic education should become more conversant with this education literature. To facilitate this, we recommend that the JCEE and the CEE commission surveys of relevant dimensions of this literature, with particular emphasis on how results in this literature relate to results in the economic education literature.

The Third Edition of the Test of Understanding in College Economics

By PHILLIP SAUNDERS*

The *Third Edition of the Test of Understanding in College Economics* (TUCE III) consists of two 33-item, four-option multiple choice tests. One test covers macroeconomics, and the other covers microeconomics. The last three questions on each test deal with international economics concepts. This enables instructors who do not cover international economics in the macro course (or in the micro course) to easily omit these questions, and use the first 30 questions as a "pure" macro (or micro) test. Each test is designed to be administered in a class period of 45–50 minutes, and copies are available in packages of 25 each from the Joint Council on Economic Education (JCEE), 432 Park Avenue South, New York, NY 10016. The tests are also accompanied by an *Interpretative Manual* (written by myself, 1991) that contains detailed norming data and additional explanatory information that cannot be included in this brief report.

Like its predecessors (see Rendigs Fels, 1967; Arthur Welsh and Fels, 1969, and myself, Fels, and Welsh, 1981), *TUCE III* has two primary objectives: 1) to serve as a measuring instrument for controlled experiments in the teaching of introductory economics at the college level; and 2) to enable instructors of particular introductory courses to compare the performance of their students with that of students in other colleges and universities. Also like its predecessors, it is a joint effort of the American Economic Association's standing Committee on Economic Education and the JCEE, which raised the funds for the *TUCE* revision.

The committee responsible for selecting, writing, and editing the questions used in

TUCE III consisted of myself as Chair; Rendigs Fels, Vanderbilt University; William Walstad, University of Nebraska-Lincoln; Michael Watts, Purdue University; and Arthur Welsh, Penn State University. We began working in the spring of 1988, and developed a pool of 85 questions to be field tested during the fall and spring terms of the 1988–89 academic year. The field test questions and some preliminary field test data were reviewed by a panel of economists in December 1988.¹ The comments of the review panel and other economists and the complete field test results were then used to prepare the 33-item tests that were normed during the 1989–90 academic year.

The content and cognitive specifications for *TUCE III* (explained in detail in the *Interpretative Manual*) are very similar to the ones used for *TUCE II*, except for the previously mentioned addition of 3 questions dealing with international economic concepts at the end of each test. Despite the similarity in overall specifications, however, only 3 of the questions on the macro test and 4 of the questions in the micro test have exactly the same wording in *TUCE III* as in *TUCE II*. Nine of the macro questions and 12 of the micro questions are completely new, and the other *TUCE III* questions are revised or edited versions of questions that were on *TUCE II*. In the remainder of this paper I will briefly elaborate on *TUCE III* tests specification, item construction, the norming sample, and a preliminary analysis of the norming data. I should also point out that, in addition to the matched

*Professor of Economics, Indiana University, Bloomington, IN 47405. A longer version of this paper will appear in the summer 1991 issue of *The Journal of Economic Education*.

¹Members of the review panel were William J. Baumol, New York and Princeton universities; Edward G. Boehne, Federal Reserve Bank of Philadelphia; Marianne Ferber, University of Illinois; Kenneth H. Miltzer, AT&T; Leonard Silk, *New York Times*; and Gary Stern, Federal Reserve Bank of Minneapolis.

norming data discussed below, we have additional *TUCE* III responses from students who took only a pretest or only a posttest, and most participating schools have sent us a set of instructor questionnaire responses, a set of student questionnaire responses, and information about individual students' SAT or ACT scores and course grades that is now being coded and matched with *TUCE* III performance data. When completed, we will have a large data set that will contain a wealth of information that should permit much more detailed analyses of *TUCE* III performance than is possible at this time. Computer disks containing all data collected will be made available to researchers by the JCEE as soon as they are compiled.

I. Specifications

Each *TUCE* III question is simultaneously classified into one of six broad macro or six broad micro content categories and one of three broad cognitive categories. The main purpose of these categories is to insure coverage of the content of "typical" principles of economics courses, and to continue the *TUCE*'s traditional emphasis on testing the *application* of basic concepts and principles. Given the scope of most principles courses and the limited number of questions that can be thoughtfully answered in a single class period, several questions on *TUCE* III deal with more than one concept or principle. This makes simple content classifications difficult, and some users may want to develop classification schemes different from the ones used to develop the overall specifications for *TUCE* III.

Since individual questions in different content categories vary in cognitive classification and difficulty, no attempt should be made to make sweeping generalizations about student knowledge of individual concepts or principles based on a single question or even a small number of questions on *TUCE* III. These tests are designed so that the *total raw score* can serve as a *general* measure of economic understanding. If individual researchers or individual instructors find that the fixed-weight content specifications of these tests are not appropriate

for their circumstances, we hope that the detailed norming data provided in the *Interpretative Manual* will enable them to interpret results in different situations in a meaningful way.

The three broad cognitive categories used to classify questions on *TUCE* III are: Recognition and Understanding (RU); Explicit Application (EA); and Implicit Application (IA). One-third of the questions on each test are in each category, and roughly half of the application questions (10 macro questions and 11 micro questions) are classified as "realistic." A realistic question is defined as one that uses a quotation taken or adapted from an actual published source or a "manufactured" quotation that might easily have appeared in such a source. In 3 questions, an actual situation is described in the stem without quotation marks being used.

The main purpose of the overall cognitive specifications is to insure a large number of questions that require students to go beyond memorization and recall, and to *use* and *apply* economic concepts. Whether or not the mental processes used by students to answer these questions actually correspond to their cognitive classification cannot be known with certainty; and any question for which a student has seen the correct answer can become a memory or a recall question, regardless of its cognitive classification. Nevertheless, we think that under normal circumstances the *total raw score* on *TUCE* III can be a useful measure of a student's *general* ability to understand and apply economic terms, concepts, and principles. As a final point on the cognitive categories used for *TUCE* III, it should be emphasized that there is no necessary or direct relation between the type of thinking or type of knowledge being tested and the difficulty of a particular question. There are hard questions as well as easy questions in each cognitive category.

II. Item Construction

Two sample questions are shown below to illustrate how individual test items are constructed on *TUCE* III. The data following

each sample question approximate overall mean performance and show the percentage of students in our norming samples selecting each alternative before (pre) and after (post) they took a principles of economics course; the point biserial correlation between the mean score of those selecting the correct alternative (shown in boldface) on that question and the mean score of the total norm group on the appropriate form of *TUCE* III (R_t); and the point biserial correlation between selecting the correct alternative on that question and the mean score on the other questions in the same cognitive category on the appropriate form of *TUCE* III (R_c).

Macro Question #8. Cognitive category "RU."

In comparing an increase in government spending on goods and services to an increase in private investment spending, we can correctly say that in the short run:

- A. they will both shift aggregate supply.
- B. they will both shift aggregate demand.**
- C. government spending is inflationary; private investment is not.
- D. government spending must equal taxes; private investment must equal saving.

Pre	Post
25%	17%
29%	50%
22%	15%
24%	18%
$R_t = .20$	$R_t = .38$
$R_c = .33$	$R_c = .44$

Micro Question #9. Cognitive Category "EA."

If all of the firms producing a product in a perfectly competitive market are required to adopt antipollution devices that increase their cost of production, one would expect:

- A. the demand for the product to fall.
- B. the market supply curve to shift to the left.**

- C. the long-run economic profits of the individual firms to fall.
- D. the short-run economic profits of the individual firms to remain unchanged.

Pre	Post
11%	9%
39%	56%
36%	25%
14%	10%
$R_t = .33$	$R_t = .44$
$R_c = .43$	$R_c = .50$

Both of these questions illustrate the point that, unless there was a strong reason for doing otherwise, all of the alternatives on each question of *TUCE* III are arranged uniformly from the shortest to the longest. This was done so that the longest alternative, which some "test-wise" students may think is usually the correct alternative, does not "stick out" and call attention to itself. Further, special care was taken to insure that each of the alternatives (A, B, C, or D) is the correct option the same number of times (8) with the exception that, on a 33-item test, one option has to be correct 9 times. On the macro *TUCE*, the "extra" option is "A," and on the micro *TUCE*, it is "D". This again was done on purpose, since another rule of thumb that test-wise students sometimes use is that examiners often like to "hide" or "bury" the correct alternative in the middle of the sequence rather than expose it in one of the first or last positions. To the maximum extent possible, we sought to make the overall *TUCE* score a measure of students' economic understanding rather than multiple-choice test-taking skills.

Both of the sample questions have good statistical properties: 1) students did better on the posttest than on the pretest; 2) all the alternatives were plausible and attracted some student response; 3) the point biserial correlation (R_t) between the mean score of students choosing the correct answer and the mean total test score is relatively high; and 4) the point biserial correlation with other items in the same cognitive category (R_c) is higher than the correlation

with the total test score (R_i). Although it is not shown, both questions also had the desirable statistical property that each incorrect answer was negatively correlated with the total test score, that is, the point biserial correlation between the mean score of those selecting each incorrect answer on each question and the mean score of the norm group for the total test was negative. Also, the percentage of students choosing each individual incorrect alternative in these questions is lower on the posttest than on the pretest. A careful analysis of the detailed item data in the *Interpretative Manual* reveals that most of the individual items on *TUCE* III possess all six of these desirable statistical properties.

III. Norming Sample

The sample of schools used to collect norming data for *TUCE* III is purposely larger and broader than the sample used to norm previous editions. Two-year colleges, at which large numbers of students take principles courses, are included for the first time, and we have broader representation of other types of schools as well. Fifty-three schools provided us with enough data to compile a matched sample of 2,724 students who took the macro test at both the beginning (pretest) and the end (posttest) of the course, and a similar matched sample of 2,726 students for the micro *TUCE*. Forty-one schools provided us with both macro and micro data. Four schools provided us with macro data only, and 8 schools provided us with micro data only. The 2,724 matched macro student responses came from 92 different sections at 45 schools. The 2,726 matched micro student responses came from 96 different sections at 49 schools.

Since some sections and some schools in the norming sample used only the first 30 questions on the posttests and others used all 33 questions, our norming sample for the last 3 international questions on each test is smaller than on the first 30 questions. For the 33-question macro test, the sample is 1,324 students from 55 sections at 33 schools.

For the 33-question micro test, it is 1,426 students from 52 sections at 28 schools. Since there are some differences in the sections and the schools using 33 questions and those using only 30 questions, extra care must be used in comparing student performance on the last 3 questions with performance on the first 30 questions on both macro *TUCE* III and micro *TUCE* III. To help avoid confusion on this issue, separate sets of detailed tables have been prepared for the 30-question samples and the smaller 33-question subsamples. It is also worth repeating that data being compiled from the instructor questionnaires and the student questionnaires will later permit much more sophisticated analyses of factors affecting *TUCE* III performance than is possible at this time.

While great pains were taken to obtain a *representative* sample for norming *TUCE* III, neither the macro sample nor the micro sample is a statistically *random* sample. Some schools that were initially asked to participate in the norming chose not to do so, and some schools that agreed to participate failed to provide a complete set of data for a variety of reasons. Nevertheless, compared to the 25 schools that participated in the norming of *TUCE* I and the 36 schools that participated in the norming of *TUCE* II, the 53 schools in the *TUCE* III sample are considerably more representative of the wide range of higher education institutions in the United States today. Using broad Carnegie Council categories, 12 of the norming schools are doctorate granting institutions, 23 are comprehensive universities and colleges, 13 are four-year and liberal arts colleges, and 5 are two-year colleges.

IV. Preliminary Analysis of Norming Data

Table 1 shows the pre- and posttest mean raw scores and standard deviations on the 30- and the 33-question versions of macro *TUCE* III and micro *TUCE* III. The posttest mean scores of 14.31 out of 30 (47.7 percent) and 15.15 out of 33 (45.9 percent) on macro *TUCE* III and 15.36 out of 30 (51.2 percent) and 16.67 out of 33 (50.5 percent)

TABLE 1—PRE- AND POSTTEST PERFORMANCE
ON *TUCE* III

Test Form	N	Mean Raw Score ^a	
		Pre	Post
Macro			
30 Questions	2,724	9.18 (3.05)	14.31 (5.24)
33 Questions	1,324	10.57 (3.45)	15.15 (5.40)
Micro			
30 Questions	2,726	10.71 (3.88)	15.36 (5.67)
33 Questions	1,426	12.35 (4.59)	16.67 (6.25)

^aStandard deviations are shown in parentheses.

on micro *TUCE* III are lower than the comparable mean scores on the previous editions of the *TUCE*. Some of this difference may be due to a difference in the questions used, and some may be due to the inclusion of a broader range of schools and students in the norming sample. It does not necessarily imply that we are now doing a worse job of teaching introductory economics than we used to, but that may be a hypothesis that is worth investigating.

The pre-to-post gains of 9.18 to 14.31 (55.9 percent) on the 30-question macro, 10.57 to 15.15 (43.3 percent) on the 33-question macro, 10.71 to 15.36 (43.4 percent) on the 30-question micro, and 12.35 to 16.67 (34.9 percent) on the 33-question micro tests indicate that, on average, students do improve their understanding of college economics during their principles courses. We hope that the instructor and student information gathered during the norming process will help us identify the factors that contribute to this improvement in a way that can help us increase it.

One test statistic concerning *TUCE* III that is not shown in Table 1, but which is worth mentioning, concerns test reliability. Test reliability refers to consistency of measurement. Any test score contains a certain degree of error of measurement. For this reason, if a student were tested a number of times, the scores would be expected to vary.

A reliability coefficient may be thought of as an estimate of the correlation between scores obtained on one test at one time and those obtained on a similar test at a different time. Kuder-Richardson Formula 20 (KR20) has been used to estimate the reliability of all editions of the *TUCE*. The posttest KR20's for micro *TUCE* III (.80 for 30 items and .81 for 33 items) are higher than the reliability coefficients for any of the previous micro forms. The posttest KR20's for macro *TUCE* III (.77 for 30 items and .75 for 33 items) are comparable to the reliability coefficients of most of the previous macro forms, but not quite as high as *TUCE* II Macro Form A, which had a coefficient of .81.

As the reliability data indicate, and as most economists would expect, we found it more difficult to construct macro *TUCE* III than micro *TUCE* III. There is less consensus in the profession on macro principles than on micro principles, and this poses real problems for test construction and interpretation. Individual instructors who want to use *TUCE* III data to analyze the performance of their students should first examine the tests and their detailed specifications carefully to make sure that they are congruent with the content and purposes of their own courses. In cases where some questions do not seem appropriate, the detailed item data provided in the *Interpretative Manual* can be used to compare the percentage of students answering individual questions correctly. Given the wide range of students and schools contained in the norming sample, the detailed data contained in the *Manual* may also be more useful than a simple comparison of raw scores or percentages.

If it is determined that the overall specifications on *TUCE* III are appropriate for a particular situation, for example, the percentile data (not shown here) can be used to put scores in context in the following way. A class with a macro pretest mean score of 11 and a posttest mean score of 18 on the first 30 questions would be in the 75th percentile of individual students in both cases, whereas a class with a pretest mean score of 9 and posttest mean score of 16 on the first 30

macro questions would be in the 52nd percentile on the pretest and the 65th percentile on the posttest. Thus, a pre-to-post gain in mean scores of 7 questions would be interpreted differently in these two situations. Likewise, a class with a pretest mean of 11 and a posttest mean of 16 on the 33-item micro *TUCE* would be in the 43rd percentile of individual students on the pretest and the 49th percentile on the posttest. This would indicate that the average performance of students in this class had increased relative to the national norms on *TUCE* III. Alternatively, a pretest mean of 11 on the 33-item macro *TUCE* (60th percentile) and a posttest mean of 16 (60th percentile) would indicate that the average performance of the students had stayed constant relative to the national norms.

Providing Earth Observation Data from Space: Economics and Institutions

By MOLLY K. MACAULEY AND MICHAEL A. TOMAN*

Burgeoning interest in understanding global environmental change has greatly increased demand for remote sensing of the earth from space.¹ Over 60 percent of a \$1 billion U.S. budget to study global change during fiscal year 1991 was allocated to space-based environmental data collection, including down payment on a \$52 billion space data program, the "Earth Observing System" (EOS), planned for the next 15 years. This substantial expenditure, together with the huge technological scale of EOS (it will consist of large orbital platforms each carrying a multitude of sensors), have promoted considerable debate and alternative proposals for smaller-scale, modular spacecraft each carrying one or a few sensors. Proponents of the alternatives hold that the smaller-scale approach, in addition to being less expensive, foregoes few scale economies and avoids the "eggs-in-one-basket" risk of EOS, in which failure in launching a spacecraft or failure of one instrument on a

multi-instrument spacecraft causes failure of the whole system. Advocates of EOS are concerned that the small-scale approach not only fails to exploit scale economies but may yield much lower information content, claiming that significant economies of scope are obtainable in operating and taking measurements from sensors aggregated on large spacecraft.

In this paper we first ask whether scale and scope economies appear substantial enough, and risk small enough, to justify the large-scale approach presently envisioned.² We then ask two separate but related questions about the organization of the project, namely whether these supply attributes require the technology to be an almost exclusively governmental activity. A dearth of information about remote sensing economics forces our approach to the production technology to be heuristic rather than empirical. Subject to this constraint, we fail to find evidence of significant scale and scope effects in large spacecraft and sensor manufacturing and launch, even after taking account of risk differentials among larger-scale and smaller-scale systems (the former

[†]*Discussants:* Arthur DeVany, University of California-Irvine; Nancy Rose, MIT; James Dearden, Lehigh University.

*Fellow and Senior Fellow, respectively, Resources for the Future, 1616 P Street NW, Washington, D.C. 20036. We thank Doug Bohi, Roger Noll, Tom Hazlett, and James Dearden for comments.

¹The vantage point of space offers synoptic and simultaneous measurement of atmospheric, land, and oceanic processes. Space remote sensing measures energy reflected by the earth's surface or atmosphere; water, vegetation, clouds, and other elements have different reflective "signatures" and their measurement adds detail to understanding environmental processes (i.e., temperature change, ozone depletion). We note that data from aircraft, balloons, and analysis of ice, sediment, and other ground processes are sources of "intermodal" competition (and complementarity, as some "ground-truthing" is needed for interpreting space data).

²We acknowledge the political economy arguments that predict overwhelming political momentum for lumpy, large-scale projects even if they are economically cost ineffective (see, for example, Linda Cohen and Roger Noll, 1991, and Macauley, 1990). But the highly visible record of the nation's space program in unsuccessfully operating large projects (difficulties with the shuttle, the Hubble Space Telescope, and the space station) is already resulting in considerable rethinking of the scale of EOS (for example, see National Research Council, 1990; Ferris Webster, 1990; Bob Davis, 1990; William Ganoe, 1990; Richard Stevenson, 1990; and William Hansen et al., 1990). Our analysis is by no means definitive, but it may illustrate key considerations for the political debate.

involves low probability, high-cost consequences; the latter involves somewhat higher probability, low-cost consequences). Thus we conclude that the case appears strong for consideration of smaller-scale systems. In addition, our study suggests several implications for the role of the private sector, even if the remote sensing data are considered a public good. These suggestions range from easing entry barriers to participation in the supply of the technology and reforming data access and pricing policy to issuing "information vouchers" to scientists involved in research on environmental change.

An important caveat is that our research does not assess the value of remote sensing information, where that value is reflected in the consequences of actions taken or not taken in response to the information. The value could be in the billions of dollars (see Alan Manne and Richard Richels, 1990, and William Nordhaus, 1990, for general discussions of information value regarding climate change). Savings in social costs attributable specifically to space-based information, however, would only be a part of the total value of information, and would depend on the space data being received and interpreted in a timely enough fashion to affect decision making (Marcia Smith and John Justus, 1990, emphasize this point). A better understanding of the value of the heterogeneous output provided by remote sensing is an obvious extension of the research in this paper.

I. The Supply of Space-Based Remote Sensing

A stylized representation of the supply of earth observation and information processing includes four vertically related stages: 1) spacecraft and sensor manufacture; 2) spacecraft system launch; 3) sensor system operation, signal transfer to ground stations, and primary processing of information; and 4) "value-added" processing and dissemination of imagery. Our 1990 paper contains details of our analysis of scale and scope effects in these stages; a summary follows.

There is significant reason to believe that stage 4 approximates a constant returns

technology given the modularity of workstations and software. Stages 1 and 2 exhibit some scale effects from the spreading out of fixed R&D and facilities costs (in stage 1) and launching larger-mass payloads (stage 2). Several factors attenuate these economies, however. Most notably, economies from multiple production are likely to be limited. Although the 15-year time frame envisioned for space-based environmental monitoring by EOS will require replacing spacecraft during the period, replacement is to occur only roughly every 3 to 5 years. Thus even if scale economies are present, they may not be exploited in small-scale production runs.

The principal issue in system launch is the tradeoff between launching a large platform with many sensors or dividing the sensor suite among several smaller platforms. There are some scale economies in launching larger-mass payloads (see our 1989 article). However, dividing the sensor suite among several launches may reduce the risk of system failure from an unsuccessful launch and also provide flexibility in subsequently replacing or upgrading components of the sensing system.

Potential economies in stage 3 hinge partly on whether larger systems can be operated at lower cost or provide higher quality data than smaller systems. Conventional wisdom holds that simultaneous measurement by different sensors is required for mutually referenced and coordinated data. However, alternative methods distribute sensors over a large number of smaller spacecraft, steer these in tandem, and filter out referencing errors in more intensive ground processing. Other economies at this stage center on transmission and initial processing of the data. These operations may be more economical on large rather than small spacecraft if scale and scope effects are obtainable by consolidating total power requirements.

How large the potential economies in stage 3 must be to justify a large-scale approach such as EOS is suggested by available information about the cost of various alternatives. EOS requires 6 large spacecraft and some 90 instruments; proposed

alternatives involve as many as 60 smaller spacecraft and 60 to 75 instruments. A comparison of the ratio of hardware and launch costs to the number of instruments (a rough measure of a system's information content) suggests significant diseconomies of scale with systems involving large spacecraft or a large number of medium spacecraft. While absolute costs may be understated (as is typical of space projects), we suspect that relative costs of alternatives are good approximations to relative orders of magnitude. On this relative basis, the larger systems are about three times more expensive than more modest alternatives. If this observation is correct, then the more costly approaches must offer some combination of significant operating economies and higher-quality data to justify these substantial hardware and launch cost differences.

Using available engineering data, rough calculations of the cost magnitudes involved in launch or instrument failure reduce the cost effectiveness of some of the smaller-scale alternatives (essentially because these systems require the success of more events: in one case, 60 launches). However, our probability calculations ignore differences in the relative importance of various instruments. For example, the loss of data could be minor if less critical instruments failed. An important extension of our analysis would involve calculating more accurate estimates of risk premia that incorporate weights based on the expected information content of various components of the proposed systems.

II. Policy Issues

Despite the lack of conclusive empirical information, enough hints about the workability of smaller-scale, more modular systems can be found in the technical literature to suggest that this option warrants serious consideration before the substantial sunk costs of a system the size of EOS are incurred. If small-scale systems are viable, then much of the argument for an exclusive role of government to remedy market failure due to scale and scope effects in the supply process is undermined. (Even if the

data provided by the program are viewed as pure public goods, then the private sector might be beneficially involved to a greater extent than currently planned.) At least three policy implications follow from these observations.

First, entry by smaller-scale operators serving niche markets (for example, hydrologic forecasting, forest inventory) could be possible without undue duplication of facilities or problems of coordination in the use of fixed facilities (say, launch sites). However, encouraging entrepreneurial entry would require the dissolution of present entry barriers, including legal restrictions on remote sensing data access and discriminatory pricing. In addition, ready access would need to be provided (at user cost) to existing public facilities like launch sites and communications networks.

Second, even if scale economies are deemed important enough to require a large-scale system, the U.S. government could encourage entrepreneurial entry by operating the system as a joint venture (again, after reducing artificial entry barriers). Any operator could locate a sensor package in the system by paying the appropriate cost that the entry would cause the system to bear.³ This approach combines competitive rivalry in serving end-use markets with the reaping of any economies from larger-scale facilities. (Some coordination among independent operators would still be required to achieve efficiency in the use of fixed facilities; for incentive compatible solutions to coordination in the case of the space station, see Jeffrey Banks et al., 1989.)

A third possibility is to provide subsidies in the form of "information vouchers" to those seeking earth observation information for stipulated public good purposes. Recipients could use the vouchers to procure information they deem most suited to their needs (including non-space-based data) and would share in any resulting cost savings

³Some evidence of private sector willingness to sponsor sensors has been documented in a recent NASA program, the Earth Observation Commercialization Applications Program.

(Macauley, 1989, applies a voucher approach to the supply of launch services to the science community). This scheme might be difficult to use if scope economies turn out to be so substantial that voucher holders could succeed only by seeking their own joint ventures with other users or suppliers. Yet the resulting transaction costs might be manageable (and they would most likely not exceed transactions costs already implicit in the centralized approach to EOS now being taken) or the scope economies might not be so substantial. If feasible, this approach could provide a useful dose of economic incentives to users and suppliers of earth observation information.

Trading Orbit Spectrum Assignments in the Space Satellite Industry

By HARVEY J. LEVIN*

Is it feasible to trade rights to use orbital slots and associated satellite frequencies in a market? Can such rights be delimited today? What is the role of international organs like the International Telecommunications Union (ITU), national agencies like the Federal Communications Commission (FCC), or the United Kingdom's Frequency Planning Organs (FPOs)? What evidence is there that such rights or assignments are in fact configured now and do indeed exist? Are they frequently traded in international as well as domestic broadcast and mobile radio services?

Even if practical and viable, what economic policy or equity purposes are served by configuring actual markets for transferable or exchangeable orbit spectrum assignments? Or for schemes where national or international authorities distribute such assignments under competition or specifically by auction to the highest bidder? That is, through public as well as private auctions? Do auctions in any case further distributive equity and not just economic efficiency?¹

I. The Tongasat Episode

The latest evidence on spectrum value probably derives from the Kingdom of Tonga's proposed orbit slot auctions. In fact, all 16 "slots" Tonga laid claim to this past year are still subject to approval by ITU's International Frequency Registration Board

(IFRB). (See Edward Andrews, 1990, p. A-1.) Today, the estimated asking price is roughly \$2 million per slot, per year (see Andrews, p. C-17). Even a few years back, comparable references could have been made to a growing number of then-proposed joint space ventures, and later of slot auctions.

A still unanswered question is whether Tonga literally sought applications for all 16 remaining slots over the Pacific to transform the ITU registration process into a mechanism for financial speculation in the geostationary orbit. And, whether, as a consequence, those applications will operate to subvert the stated purpose of ITU's Radio Regulations, or of the Union itself, or, in particular, of Articles 4 and 29 of the ITU Constitution.

Of special interest were a number of "unsolicited offers to Intelsat, and undoubtedly to others, proposing lease or other arrangements for...use of the slots." As perceived by Intelsat, Tongasat's press releases, offering statements, and mass filings with IFRB are mainly geared to "gain...control over an excessive number of orbital slots which could then be speculated in or sold for financial gain." (Letter from Intelsat Director General Dean Burch to Members of IFRB, June 12, 1990, p. 1.) The main issue is whether Tongasat is applying for orbital slots far in excess of its projected economic needs. If so, is the orbital arc being "claimstaked" to prevent "other ITU members from registering and using the orbital slots for legitimate purposes without financial remuneration to Tongasat"? (Letter, p. 2.) Does Tongasat intend to distribute "orbital slots by selling or auctioning them to the highest bidder"? If so, is this "hoarding of orbital locations and associated frequency spectrum...contrary to the spirit of Article 29 of the ITU Constitution (Nice, 1989)"? (Letter, p. 2.)

*University Research Professor and former Augustus B. Weller Professor of Economics, Hofstra University, Hempstead, NY 11550.

¹For recent evidence on spectrum value and market-type transactions in New Zealand, see *Treasury Submission...*, 1985; Robin Foster et al., 1988; Charles Jackson and Foster, 1989; Nancy Kuehl, 1990. On the economics of spectrum allocation in other countries outside the United States, see OECD, 1990; CSP International, 1987; *Wall Street Journal* editorial, 1990; and Government of Canada, 1990.

There is in any case a widespread international consensus apparent in the Radio Regulations and many ITU resolutions that the geostationary satellite orbit, and associated radio frequencies, are without question scarce natural resources owned by no one nation but rather by all. These resources are subject to standards of economic efficiency and equitable allocation among all nations in meeting their legitimate communication needs. The big question is whether the slot and spectrum auctions envisioned by Tongasat will facilitate or impede the furtherance of equity and efficiency as criteria for satellite regulation and orbit spectrum management.

II. The Pacstar Joint Venture

Let us take note of the recent proposed joint venture between the TRT Telecommunications Corporation's subsidiary Pacific Satellite Inc. (PSI) and the Papua New Guinea (PNG) Public Telephone and Telegraph Co.² There, PNG notified the IFRB 2 years beforehand, *on behalf of PSI*, that PSI would use two PNG orbital assignments in return, giving PNG free domestic circuits in return. In this scenario, the developed country (DC) entity virtually *borrowed* an unused developing country (LDC) assignment to illuminate part of the DC's market. In return, it would pay the LDC in kind with *free* transponders or reduced-rate domestic circuits, at low incremental cost to the DC firm, once the latter's satellite was in place.

In all such cases one could say that LDCs are already finding ways to lease out, lend, or otherwise trade their orbit spectrum assignments; and to do so for a portion of Intelsat's revenues (14 percent return on investment); or for a comparable return on regional investment by an Arabsat, Andeansat, or Euthelsat.

The advantage to Pacstar in using PNG's assignment is twofold. First, it would pre-

sumably get "better" (less costly) coordination under ITU with joint support and sympathy in the South Pacific. Second, it might thus avoid being thrown into the large pool of applicants at FCC, including proposals for a North Atlantic service. Processing that full queue would take a long time, and lots of money. If Pacstar had to wait its turn on line it might well have far more trouble in getting preferred assignments than if PNG applied for them directly instead.

The engineering expertise, and *intimate knowledge of international regulatory-coordination procedures* that Pacstar brought into the joint venture, plus avoidance of the FCC queue, have doubtless resulted in important cost savings. These were in turn exchanged for free domestic satellite circuits for PNG. Hence PNG's slot value may have been created by international administrative sluggishness or simple incompetence in dealing with ITU and IFRB direct.

In the Pacstar case, PSI wanted to create a system in the South Pacific and arranged for its origin spectrum assignment in a then-unique way. Instead of waiting in line at FCC, the ITU, or IFRB, PSI sought to avoid such delays by entering directly into a Joint Venture with a third party, PNG, or more accurately its PTT.³ As part of the bargain, PSI would give PNG one free transponder in perpetuity, and maybe the Tracking, Telemetry & Control Module (TTCM) too, though not the cost of operating it. So the question is what it would cost PNG to *operate* the TTCM for its 7-year lifetime, compared to the cost of *buying* or *renting* one transponder for the same period.

III. The Panamsat-Peru Episode

In this case, the Panamsat Corporation wanted to provide diverse programming and service in the Western Hemisphere. Under FCC and ITU regulations, however, it could not gain access to the orbit spectrum re-

²On new interests and insights in satellite joint ventures and consortia and related arrangements, see The Transmart Company, 1990; UN Center on Transnational Corporations, 1988.

³Illustrative joint ventures between entities in LDCs and the United States by now include Brazil, Venezuela, Dominican Republic, Guyana, Haiti, India, and the Malaysian Republic. (See Carl Christol, 1975.)

quired. Without a foreign correspondent, that is, someone to communicate with at the other end, the corporation would simply have a right it could not use.

As traced in the trade press, Panamsat did locate a correspondent when Peru came forth. Again, as with Pacstar, Peru was paid one free transponder per year, in perpetuity, a gift worth \$1 or \$2 million annually had she had to rent it outright. Because Peru needed only one-fifth of a transponder, however, she got a little extra, and here, too, was an economic benefit of sorts.

IV. The Panamsat-Cygnus Transaction

Cygnus and Panamsat were both satellite companies. However, Cygnus was poised, anxious and authorized to serve over the Atlantic to Western Europe and the mid-East, though with no satellite equipment in orbit. On the other hand, Panamsat's hybrid satellite had 24 low-cost C-band transponders which she was already authorized to use. She also had another 12 transponders higher up in Ku-band, where it was more costly to operate, and where FCC continued to prohibit use.⁴

Accordingly, one could say that Panamsat had the needed *equipment*, while only Cygnus had the *rights* to operate in Ku-band at the same orbital location. So that Panamsat had the physical capability and the equipment already in place, while Cygnus had the rights to use all her 24 planned transponders, but lacked the equipment needed to start. Because starting from scratch at that time, and then building the needed satellite would simply take too long, Cygnus would never have made the deadline. Therefore, the two companies might have entered into some sort of agreement with one company buying the other out, or both companies creating a joint venture.⁵

⁴The FCC did not want Panamsat to use only half of its Ku-band satellite (12 transponders), preferring instead that she use a full C-band satellite of 24 transponders.

⁵See FCC, 1987; see, especially, paras. 6, 9-12.

Cygnus did in any case have advertising contacts, marketing services, client lists, and goodwill. The buyer (Panamsat) presumably had to pay for all this, and, of course, she also wanted to remove a potential rival from the field. In addition, there was something of potential value left in the bankrupt Cygnus, and the challenge was to resuscitate it when Cygnus herself could not do so.

Nevertheless, if all that remained after bankruptcy was Cygnus's bare authorization, the FCC would presumably approve the transfer at a price recovering the seller's cost of securing the original spectrum assignment (see FCC, para. 6). The transfer price would be roughly \$300,000-\$350,000. This would cover Cygnus's reasonable out-of-pocket costs including goodwill and marketing information, but nothing more, to avoid any proscribed trafficking in licenses.

V. Atlantic Star

Here the partners would be Hughes and the state of Ireland with the proposed joint venture geared to operate a direct broadcast satellite. Ireland's orbit spectrum assignment would presumably be used, thereby saving Hughes the time and money she must expend should she proceed through FCC to the ITU (see Hughes Communications, Inc., 1990). So the proposed Atlantic Star seems similar to Pacstar. In both cases, a large U.S. company (TRT or Hughes) contributes capital and know-how to a joint venture (Pacstar, Atlantic Star), whereas a remote developing island nation (Papua New Guinea), or a small European economy (Ireland), contributes the needed orbit spectrum assignments.

With Atlantic Star, Hughes proposed to hold 80 percent of the investment, and Ireland, 20 percent. The main use was to be for English or Irish language programs for Europe, the Irish getting in because of dissatisfaction with British plans and activity. But now that the British have approved their own system, the Irish seem to have faded out. So if Hughes can get contracts from both the United Kingdom and Ireland that would suffice, and there'd be no need for Atlantic Star. (See Peter Liska, 1987.)

IV. Conclusion

In addition to the five well-known episodes just discussed, market-type transactions, spectrum value, and joint ventures also figure in other cases. These involve additional joint ventures such as Japan-Communications Satellite, Asiasat, Rupert Murdoch's Sky TV-Disney Channel, or his joint venture with Luxembourg, where the latter was to provide the orbital assignment and Murdoch the broadcast satellite. Or where RCA or GT&E leases or rents unused Anik-C capacity paying Canada \$2 million U.S. annually to tilt the satellite southward until Canada herself might need that capacity in her northern regions. For several prior years, the Anik capacity enabled those companies to perform reliably before their own new equipment was orbited and operating.

Torts and Orbits: The Allocation of the Costs of Accidents Involving Spacecraft

By ANN M. BUTLER AND NEIL A. DCHERTY*

Who pays when a satellite fails to burn up in reentry and crashes in Manhattan, or when a Titan rocket fails on launch and crashes on Cocoa Beach? These are matters for courts and legislators. In 1988, the Commercial Space Launch Acts Amendments (CSLAA) capped common law liability at \$0.5 billion (with the federal government assuming the next \$1.5 billion) and made third-party insurance compulsory, as available, up to the cap. But the costs can be reallocated amongst the various parties involved in the venture. Thus "who pays" becomes an economic choice. This choice has significant implications for resource allocation and will influence the level and quality of investment in space activity. We examine economic issues surrounding the allocation of liability, particularly contract design, and the effects of insurance on market efficiency.

The main players in the commercial satellite industry are manufacturers, operators, launch contractors, and a host of supporting industries including subcontractors and insurance firms to which some risk can be transferred. To these may be added third parties who bear the risk of injury or property damage from failure of a dangerous technology, and the government whose interest stems from these negative externalities and from positive technical externalities which accrue both to private and military activities.

Liability exposure clearly shapes incentives for real investment and emphasizes the importance of contract design in allocating risk. Contract design is important because

parties differ in their abilities to bear risk and in their abilities to minimize the costs of accidents. The optimal contract trades off risking bearing against efficiency in production and loss control in the usual way.

Contract design would be simplified if insurance markets were frictionless. Contracts between operators, manufacturers, and launchers would optimally allocate liability for third-party loss, and indeed other loss, to the party who could minimize total costs. However, insurance markets are far from perfect; small numbers of satellite launches imply limited diversification for insurers and small samples from which to estimate loss distributions. Moreover, technology is constantly changing and between some losses there is a high correlation (for example, satellites on the same launch vehicle). Finally, insurance encounters significant moral hazard since the complexity of the technology makes it costly to monitor the policyholder's actions, and the small sample of events makes "reputation" an ineffective control.

A further set of issues complicates the issue of contract design but makes it more interesting. Players vary considerably in net worth, yet all face potential liabilities for third-party damage of billions of dollars. The expected gain from default on these liabilities is highest for firms with small net worth, creating an apparent diseconomy of scale. However, liability rules, such as joint and several liability, make larger firms leery of entering joint ventures with small firms. Many small firms are innovators but rely on joint ventures to supply ancillary technology, manufacturing facilities, or capital. These innovations might be lost unless small firms are able to internalize the full costs of their activities *ex ante*. This prospect defines a particular role for insurance, and against this background we can examine the effect

*Florida State University, Tallahassee, FL 32306, and Wharton School, University of Pennsylvania, Philadelphia, PA 19104, respectively. A more extensive paper is available from the authors.

of compulsory insurance and liability caps recently introduced.

I. Limited Liability, Compulsory Insurance, and Liability Caps

The common-law basis of liability for launch, reentry, and similar accidents, (for example, strict liability or negligence) is untested since there have been no such lawsuits to date. However, a clear liability exists and is internalized to the industry by common law. The size and nature of this cost depends both on liability rules and the economic characteristics of the players. The value of judgments awarded by courts rests on the ability of the plaintiffs to enforce the awards against defendants with limited net worth. With such liability costs, firm size, organizational form, and contractual allocations of liability, become strategic variables.

The commercial space market comprises players of different sizes and organizational structures, ranging from the U.S. government to individual scientists who attempt to bring to market innovative technologies based on their own research. In between are stock firms including such major players as Hughes, McDonnell Douglas, and Rockwell. The value of an award for injury to a third party depends on who the plaintiff happens to be and on the extent and quality of his insurance. First suppose that the good is produced by a single firm. We relax the assumption later.

Limited Liability with Single-Firm Production.

All producers ultimately have a limited liability for their actions. For stock firms, liability is truncated at net worth. In other organizational forms, liability may be limited by personal bankruptcy laws and the wealth of the firm's owners. We discuss stock firms, though the concepts generalize. The effect of limited liability is to create a "put" option for the firm's owners, who put the loss to the injured parties when the loss exceeds net worth (the striking price). The firm's long position in the put increases firm value. The value of this put option depends on the net worth of the firm as well as its risk characteristics. The option will be more

valuable to small and risky firms than to large and stable firms. This creates a distinct cost advantage to small firms.¹

The main implications of the cost advantage for small firms lie in organizational choices. High-risk technologies would be more likely to appear in small-size firms and existing firms would tend to "spin off" high-risk activities. In other industries, there is recent evidence that this has occurred (see A. Ringleb and S. Wiggins, 1990).

The cost advantage of small firms is unlikely to be removed by voluntary insurance. Unless third parties have a mechanism for inducing small firms to internalize the full liability costs *ex ante* through the purchase of full insurance, firms would find no advantage in insuring above their net worth (R. MacMinn and L. Han, 1990). Thus, legislation requiring insurance of third-party liability can be rationalized as removing the liability externality generated by small firms and levelling the playing field between large and small firms.

The CSLAA legislation also caps the liability of producers at \$500 million, above which the federal government assumes liability to third parties for the next \$1.5 billion. The effect is to formalize the externality but to transfer the external cost from potential victims to the government. The cap is redundant for firms with net worth below \$500 million but it generates a subsidy to larger firms, the value of which increases with firm size. As with the compulsory insurance provisions, the gain from caps accrues to large firms.

The preceding analysis provides an apparent rationale for the CSLAA requiring compulsory insurance. The CSLAA recognizes the apparent limits of the insurance market (coverage is seldom available for single losses in excess of \$500 million) and

¹This advantage rests on the assumption that it is costly for third parties to contract with producers. This situation may be contrasted with labor contracts where the proximity of the relationship between employee and employer, the presence of a bargaining structure and a preexisting contract relationship imply that labor can extract compensation for risk *ex ante* in the form of a risk premium in the wage.

provides a more orderly system of compensation for large losses that fall on the federal government. The Act creates a subsidy to larger firms by removing liability above the cap. While this will undoubtedly encourage higher levels of investment, whether this will lead to a more efficient allocative solution is unclear. By itself, the creation of the externality will lead to excessive investment. However, the broader policy objectives recognize the presence of substantial positive technical externalities or "spinoffs" which arise from space technologies.² Nevertheless, the benefits of the Act appear to be loaded entirely in favor of large firms. Small firms are now required to internalize the liability cost and receive no immediate benefit from the cap. Consequently, the Act apparently will deter entry of small innovative firms.

Liability Analysis with Joint Production.

The assumption that production is undertaken by a single firm is unrealistic. The technology is complex and costly, and virtually all enterprises involve many types of firms: the operator of a satellite, the launch contractor and the many subcontractors that construct the launch vehicle and its components, the satellite manufacturer and its subcontractors, as well as governments who approve and monitor the operations of the satellite. A large liability claim is unlikely to result from the negligence of a single firm but from the contributed negligence of several. Under one resolution of multiple negligence, firms may be jointly and severally (J&S) liable. Under J&S, damages may be apportioned among defendants according to the respective degrees of negligence. However, each can be fully liable for all damages. Thus should one highly culpable party become insolvent, a less culpable firm with substantial net worth may find itself fully liable for all damages. Without J&S, each firm's damages is limited by the degree of negligence it has displayed. In some jurisdictions and/or some torts, J&S operates; in others it does not.

If J&S does not operate in this setting, our analysis of CSLAA is unchanged by the introduction of joint production. If J&S does operate, it will affect contractual relationships materially. Larger solvent firms will be unwilling to commit to joint operations with small firms, unless the latter are able to internalize full liability costs *ex ante*. One way small firms may do this is by the purchase of insurance with limits in excess of net worth. Insurance may be purchased on the conventional insurance market from outside insurers. Alternatively, recognizing that large firms effectively insure the default risk of smaller coproducers under J&S, this transfer can be formalized in a hold-harmless agreement and priced accordingly. While we argued that insurance coverage in excess of net worth would not be rational under the assumption of single-firm production, this strategy is privately optimal under the assumptions of joint production and J&S liability.

The price of entering a joint venture will be higher for financially weak firms. Financially strong firms can require more risky collaborators to purchase adequate insurance. Alternatively, strong firms can supply that insurance and reflect its price in contract terms. In this way, investment in safety and loss control will be conditioned more by social costs (i.e., by expected liability) than by the wealth of the actors. With external insurance, the liability cost is internalized *ex ante* to the small firm in the insurance premium. This transfers the incentive to monitor loss control to the insurer. If the insurer is an efficient monitor, social costs will be reduced by insurance. However, given the complexity of technology, the importance of design and quality control, an *a priori* case can be made for permitting large contractors to assume the monitoring role by assuming full liability in the event of default of their collaborators.

This reasoning provides an economic rationale for J&S liability in an industry characterized by joint production. However, J&S has been criticized on allocative criteria. While it is socially desirable to internalize the liability costs jointly to those involved in production, the *ex post* allocation of liability

²See NASA 1990 annual publication *Spinoff*.

cost between the joint defendants under J&S may bear little relationship to *ex ante* behavior. Thus, J&S appears to send arbitrary cost signals. However, once we recognize freedom to contract *ex ante*, the incentives created by J&S begin to make more sense. J&S gives each firm an incentive to monitor both the loss control (safety, quality control, etc.) and the financial condition of its collaborators. Moreover, under joint production, firms with limited net worth will be required to internalize the full liability cost *ex ante* by the purchase of insurance from external suppliers or from coproducers.³

II. Conclusions

Legislation seems to be motivated by fear that uncapped liability would cause underinvestment in space enterprises and there would be a consequent failure to reap positive technical spinoffs. Liability caps counter this incentive by creating a countervailing negative externality. A second motivation is the fear that third-party victims would not have enforceable claims in tort. However, the compulsory insurance aspects of the legislation may be, at best, redundant. While liability costs appear to be externalized through the effects of limited liability, the operation of joint and several liability provides a common law alternative to compulsory insurance. Given the joint production aspects of space technology, the assumption

of liability for defaulting collaborators gives each firm an incentive to monitor coproducers and to price this default risk in joint venture contracts. Since compulsory insurance affects mostly small firms, it is likely that they would have assumed the default risk anyway *ex ante* by purchase of full insurance, or by selling this risk to collaborators in joint ventures. If insurers were better able to spread this risk and monitor safety aspects of production, then the price of entry to joint venture could be lowered by all firms fully insuring. The Act replaces this negotiable option in favor of mandated insurance. Not only is the insurance industry probably a less efficient monitor, but the infrequency of losses denies to insurers the usual mechanisms for controlling moral hazard.⁴

⁴Insurers often use experience rating to control for moral hazard when the exposure is often repeated. However, for satellite risk the sample of observations and losses is too small and thus has a high "noise-to-signal" ratio.

³L. Kornhauser and R. Revesz (1990) have recently argued that, with joint tortfeasors and the potential for insolvency, one cannot make a general statement about the efficiency aspects of J&S. Our stronger statements about the efficiency effects of J&S relate to the current narrowly defined problem. We do not imply here that they can be generalized.

The National Aerospace Plane: An American Technological Long Shot, Japanese Style

By LINDA R. COHEN, SUSAN A. EDELMAN, AND ROGER G. NOLL*

In the mid-1980's, the United States embarked on a most ambitious government research and development (R&D) venture, the National Aerospace Plane (NASP). NASP's goal is to build a piloted research plane, the X-30, that will travel 25 times the speed of sound, use normal airports, and fly to near-earth orbit. Moreover, the program's organization has a distinctly Japanese form: five government agencies and five companies that might have competed for the program are collaborating on a single design.

This paper examines the match between NASP's technical challenges and its political and organizational incentives. We conclude that the technical basis for NASP is shaky, and that its organizational innovation increases the chance of failure.

I. The Political Economics of R&D Programs

The positive economic theory of government R&D programs is based on three results from the rational actor model of politics (see Cohen and Noll, 1991). First, voters evaluate incumbent politicians retrospectively (what have politicians done for us lately?), causing incumbents to favor programs with immediate payoffs. Second, because citizens largely organize political participation around groups, political actors favor programs that deliver visible rewards to organized interests. Hence program expenditures are often political benefits rather than costs. Moreover, when dealing with an industry, political actors prefer a program that distributes benefits among all industry participants, rather than one that picks winners or otherwise disadvantages some firms. Third, because incumbent politicians have

high probabilities of reelection, they fear political mistakes more than they value political windfalls. Hence, they seek to avoid programs with risky benefits.

All of these characteristics make R&D politically unattractive. R&D usually has a long time horizon with uncertain payoffs, and can upset wealth positions in industry. If the most efficient structure of an R&D program is to centralize management, the prime contractor may gain a competitive edge. Finally, the distributive benefits from contract expenditures are smaller in the early research phase, so that political leaders have an incentive to speed up research in order to get on with the big-ticket prototype and demonstration phases. Insufficient research lowers the expected net benefits of a program.

Industrywide collaborative ventures deal with some of the political problems of R&D projects. Most clearly, they minimize the disruptive act of "picking winners." Because collaboration lowers the likelihood of independent R&D by each collaborator, it reduces the chance that the project will fail because someone else invents something better. Nevertheless, collaborative government R&D ventures have been rare. The Clinch River Breeder Reactor involved a large number of utilities, and Sematech includes most of the semiconductor industry. But other ventures, notably other commercial aerospace ventures (satellites, supersonic transport, Space Shuttle) used competition among several contractors. In the case of satellites, steadfast pursuit of a procompetitive policy caused an otherwise successful program to be cancelled (Cohen and Noll, ch. 7).

Collaborative ventures have two undesirable characteristics. They narrow the range of alternative paths of development that are explored and can cartelize the industry. The first becomes a political cost if the collaborators produce no worthwhile advance, but

*University of California, Irvine, CA 92717; Columbia University, New York, NY 10027; Stanford University, Stanford, CA 94305, respectively.

other promising paths go unexplored or, even worse, are developed by foreigners. The second is politically costly if cartelization becomes a political issue, such as might occur if the collaborators sell to another politically influential industry. In the past, political actors have eschewed the collaborative approach. However, the principle has become fashionable in government, and is a major component of the recent technology policy plan issued by the White House, which calls for antitrust exemptions and other policies to promote R&D joint ventures in response to perceived Japanese successes on "critical technology" fronts (Office of Science and Technology Policy, 1990).

II. The NASP Program

The NASP program dates to 1984, when the Defense Advanced Research Projects Agency (DARPA) became convinced that hypersonic technology was worth pursuing (T. A. Heppenheimer 1987). During 1985, four other agencies were brought into the program: Air Force, Navy, National Aeronautics and Space Administration (NASA), and the Space Defense Initiative Organization (SDIO).

Two technical advances made DARPA enthusiastic about the program. One was in scramjets—air-breathing engines capable of hypersonic flight. Air-breathing engines, unlike rockets, need not carry oxygen for fuel combustion, and so reduce weight at take-off. The second advance was in materials. Very high speeds cause an airplane to become extremely hot. The challenge is to create strong, heat-resistant, lightweight materials.

System integration issues also present significant challenges. To exceed speeds of about Mach-7, the plane must use hydrogen slush as a fuel. This requires building tanks and pipes for storing and delivering hydrogen to the engines. Moreover, the slush will be used to cool the craft. Constructing the fuel and cooling systems is not trivial. Another system integration issue concerns airframe design. Scramjet engines must be extremely long, or else the air (traveling at Mach-25) and fuel will not combust inside the engine. Engines are part of the airframe

and affect airflows (and lift and drag); very large engines present an unsolved fuselage design problem. Finally, the program places heavy reliance on computer simulations. Current wind tunnels simulate conditions only up to Mach-7; to test the plane requires actual flight. Flight simulations require unprecedented advances in computer fluid dynamics.

In sum, NASP leaps into uncharted technical waters. Mach-25 is more than three times faster than the existing speed record for experimental aircraft and seven times faster than any aircraft has flown in sustained flight. Every important element of the program attempts a radical advance of known technology.

The NASP management is also innovative. Initially, five aircraft and engine firms independently pursued designs. In May 1990, the groups working on NASP within each firm were merged into a single "team" that shares all technical results and is formulating a single design incorporating features of each firm's past work. The team members have cost-plus-award contracts with the government, and will share the award (profit) equally, regardless of the ultimate division of work ("Teaming Agreement Stresses Equality Among Five NASP Prime Contractors," 1990).

The management form increases the riskiness of an already risky project. Exactly one engine, airframe, and fuel system will be developed for a radical technology. Moreover, the incentives for each contractor to devote best efforts to the project are diminished by severing the tie between technical contribution and shares in profits and information.

III. The Politics of NASP

To understand the politics of NASP requires identifying the reasons each major player participates in the program. The aircraft industry receives several hundred million dollars per year for research on advanced engine and airframe design, and will get substantial contracts once construction of the X-30 begins. Industry will benefit regardless of whether the X-30 reaches orbit or even flies.

The rationale for government is more complex. Because of the high costs and risks of the program, none of the agencies involved has been willing to commit to it to satisfy policy missions. The committee approach, however, has been (marginally) acceptable to the agencies; more importantly, it created a broad coalition favoring NASP within Congress and the White House.

The Air Force and Navy entered the program during the era of the "evil Empire," and so were motivated by the arms race. The end of the Cold War reduced the budget for defense R&D. Although reversed by both the White House and Congress, the Air Force attempted to pull out of the program in 1989, proposing to reallocate the budget to other defense programs (Craig Covault, 1989; U.S. House of Representatives, 1989).

NASA, whose top priority is piloted space flight, has a far greater stake in the program. The agency's present technology (the Space Shuttle) borders on fiasco. However, NASA steadfastly maintains that NASP is a research venture without an explicit mission and not a substitute for other advanced launch technologies. SDIO currently is pursuing a separate single-stage-to-orbit vehicle (James Asker, 1990). DARPA was too small from the start to continue its more limited program in scramjets.

Coalitional support means the program must demonstrate technology that relates to the missions of the different agencies. Follow-on military applications require sustained hypersonic flight; space applications must attain orbit. The latter requires the X-30 to fly not just hypersonic, but at Mach-25; additionally, the current design calls for a rocket to be incorporated into the aircraft for the final thrust to orbit. Satisfying NASA's congressional overseers requires the X-30 to be piloted by people (U.S. House of Representatives, pp. 51-52).

Our analysis suggests a paradoxical relationship between agency budgets and project scope. When agencies are rich, they can pursue small projects with narrow objectives. For example, NASA's initial foray into geosynchronous satellite technology occurred in the early 1960's when government enthusiasm for space-related activities sur-

passed NASA's ability to spend. Alternatively, poor agencies need to mobilize large coalitions and consequently pursue ambitious programs with multiple objectives. The government team approach for NASP increases the technical complexity of the program, and significantly raises risks of failure along any dimension.

The NASP program's management strategy, consistent with efficient sequential decision making for R&D, is to postpone the decision to build the X-30 until the design phase is successfully completed. Unfortunately, the government cannot commit to cancel the program should the design phase produce bad news. NASP's two most recent aerospace predecessors provide sobering examples. The initial supersonic transport (SST) design proved infeasible, and the plane's performance characteristics never lived up to initial goals (Edelman, 1991). The SST had the same management plan as NASP, but was not killed until 1971, not because of performance shortfalls (which had been known for 5 years), but because of opposition from environmentalists at the peak of their influence in Congress. Similarly, the component that made the Space Shuttle's *ex ante* expected net benefits positive (the Space Tug, a vehicle carried in the Shuttle's bay that could fly to geosynchronous orbit) proved technically infeasible prior to construction of the shuttle fleet (Jeffrey Banks, 1991).

Whether NASP can be cancelled if the design results are discouraging depends on the incentives facing Congress and the president. Both are likely to focus on aspects of the program of less concern to the agencies. One is the symbolic value of the technology. The other is the political value of NASP contracts. Our work on other large R&D programs finds that political support for continuing failed projects is significantly affected by the magnitude of current expenditures.

The symbolic value of the program has found continued expression among political supporters. President Reagan announced the program in his 1986 State of the Union address, when he spoke not of the need to support R&D in the aircraft industry but instead of the "Orient Express" of the

twenty-first century—a plane that would allow passengers to fly from New York to Tokyo in an hour or two. Congress has focused on specific applications, such as replacing the Space Shuttle or building a reconnaissance plane as fast as a missile despite the fact that these objectives could be achieved more cheaply and with greater certainty by other technologies (Stephen Korthals-Altes, 1987; Bruno Augenstein and Elwyn Harris, 1989; Office of Technology Assessment, 1989). Industry regarded the team approach as increasing the political feasibility. According to Barry Waldman, leader of the industry team, “If we don’t pull together, we don’t get to Phase 3,” the high-budget construction of X-30s (“Teaming Agreement...,” p. 38). Attempts to stress that the program is pure R&D are inconsistent with the basis for its political support, and so are probably irrelevant. To cancel the program after the design stage would not only harm the contracting companies, but would prevent attaining a symbolic accomplishment that political leaders could use to their benefit.

IV. Conclusions

It is unlikely that NASP will be more than the agencies contend: an exciting research venture that will produce new aviation technology and, if the X-30 flies, set new speed records. Nonetheless, the program has been designed to produce another technological turkey reminiscent of past big-ticket failures. The innovative “team” approach makes the program more difficult to kill if NASP becomes nothing more than an expensive toy. Involving all of the important players in the aerospace industry eliminates short-term sources of political attack because it picks no winners and has no competitive external R&D effort. Involving multiple government agencies creates a stable support coalition within government.

The NASP program’s organizational structure is born of political forces, not technical and economic optimization. High-risk projects call for incremental development, flexible management schedules and the ability to explore many technical paths before committing to a system design.

Thus, the “Japanese-style” government-industry collaboration serves political needs at the expense of expected program performance.

TORT LAW AS A REGULATORY SYSTEM[†]

Regulation and the Law of Torts

By SUSAN ROSE-ACKERMAN*

Tort law is "private" law. Regulation by statute is "public" law. How should the two relate to each other in a regulatory state where statutory intervention in private markets is widespread? Both tort and statutory law have regulatory effects. Thus economic policymakers should examine the links between these legal regimes in substantive areas where both systems operate. I argue in this paper that statutes should generally dominate so long as agencies can use rule-making to shape policy. Common-law torts should be limited to areas of activity not covered by statutes and to situations in which courts can complement the statutory scheme with a supplementary enforcement and compensation mechanism. However, if the implementation of a statutory scheme requires that private tort actions be preempted, alternative methods of compensating victims, such as social insurance or statute-based private damage actions, may need to be designed.

I. Torts vs. Statutes

The fundamental differences between tort law and regulation center not on substantive standards, or on the distribution of benefits and harms, but on procedures. Statutory regulation, unlike tort law, uses agency officials to decide individual cases instead of judges and juries; resolves some generic issues in rulemakings not linked to individual cases; uses nonjudicialized procedures to

evaluate technocratic information; affects behavior *ex ante* without waiting for harm to occur, and minimizes the inconsistent and unequal coverage arising from individual adjudication. In short, the differences involve who decides, at what time, with what information, under what procedures, and with what scope.

Steven Shavell has developed a useful four-category schema to organize a discussion of alternatives (1987, pp. 277-90). He distinguishes between *ex post* (backward-looking) and *ex ante* (forward-looking) options, and between privately initiated and state-initiated systems. This framework produces four alternatives: Tort liability (*ex post*, privately initiated); court injunctions (*ex ante*, privately initiated); command-and-control regulation or corrective taxes (*ex ante*, state initiated); and fines for harm done (*ex post*, state initiated). For our purposes, the most important comparisons are between tort liability and *ex ante*, state-initiated approaches.

Five factors, according to Shavell, should influence the choice between *ex ante*, state-initiated and *ex post*, privately initiated approaches. First, state action is desirable when the harm is so diffuse that individuals have little incentive to sue on their own and cannot cheaply organize to sue as a group. Second, if injurers are too poor to pay for the harm they cause, a system based on *ex post* payments will not effectively deter them. Third, when harm can be demonstrated on a statistical, but not an individual, basis, regulations or taxes applied *ex ante* can shape behavior without a showing of causal links between particular parties.

Fourth, an *ex ante* regulatory system will be preferable when the same information about costs and benefits is relevant to many

[†]*Discussants:* Roger Noll, Stanford University; George Eads, General Motors Corporation; Robert Crandall, The Brookings Institution.

*Ely Professor of Law and Political Economy, Yale University. This paper is adopted from my forthcoming article (1991).

instances of harm. Fifth, administrative costs are an important consideration. If the probability of harm is low, *ex post* systems may be preferable since they only need come into play when damage occurs.

Ironically, tort law may be most ineffective in precisely those areas where judicial doctrine has been most innovative—toxic torts, products liability, and medical malpractice. These are all areas where *ex ante* regulation enjoys distinct advantages. Some critics, such as Peter Huber (1988) and W. Kip Viscusi (1984), point to the courts' incompetence concerning technical issues of health and safety—incompetence arising from lack of expertise, inadequate staff, and procedures ill-suited to the discovery of scientific truth.

Nevertheless, widespread support for the tort system persists even when the logic of efficient risk control demands *ex ante* regulation. Given this reality, the remainder of this paper attempts to explain how torts can be used to further, not distort, deterrence goals and isolates those situations where preemption would be desirable.

II. Torts as a Complement to Statutory Regulation

Let us consider, then, a situation favoring statutory regulation over torts—for example, the safety of automobiles, drugs, or medical devices, where many people are at risk and information about product design is often relevant to harm. To highlight the differences between statutes and torts, assume that regulatory standards are set through rulemaking under a command-and-control scheme.

Ideally, tort law and regulatory standards work together to further deterrence and compensation goals. Torts and regulations can be complementary: 1) when tort doctrines are stopgaps which apply absent more stringent statutes; 2) when regulatory standards are intended as minima which more stringent tort doctrines can supplement, and 3) when a regulatory standard is set at the socially optimal level and tort doctrine imposes either strict liability or a standard of care lower than that required by the agency.

However, when the regulatory standard is set optimally while the tort standard of negligence is interpreted to require an even higher level of care, conflicts can arise under a system of compensatory damages. Such conflicts are even more likely when punitive damages are available.

Legislatures have other aims besides constructing rational regulatory systems, and they often fail to establish regulatory programs in all of the areas in which regulation would in theory be superior to tort law. In such cases the first type of complementarity applies. Courts should not idealize the pattern of common-law regulation created by their past adjudications, but should instead see tort law as a stopgap pending future statutory regulation. "The common law standard of [reasonableness]...can at least serve the needs of our society until the legislature imposes higher standards" (*Larsen v. General Motors*, 1968, p. 506). If a regulatory statute is then passed, courts should resolve conflicts between tort doctrines and regulatory principles by according priority to the statute (*Wood v. General Motors Corp.*, 1989, p. 402).

Regulatory standards are sometimes designed to establish only a baseline. Then the second case holds. While violation of such a standard usually amounts to negligence per se in a tort suit, compliance with the standard is merely evidence for the jury to consider in determining reasonable conduct. Note the asymmetry here. Because the standard sets a minimum, the plaintiff can argue that a higher standard should be imposed in a particular case, but the defendant cannot invoke special circumstances to justify its violation of the basic standard.

The courts have taken this approach in product and occupational safety cases; they have ruled, for example, that the Food, Drug and Cosmetic Act sets only minima and does not preempt tort suits for damages. Similarly, tort suits involving automobile design or exposure to nuclear materials (*Silkwood v. Kerr-McGee*, 1984) are not preempted by regulatory statutes.

These first two ways of reconciling tort law and statutory law are logically inconsistent but coexist in practice; tort suits with

regulatory effect are permitted both when the legislature has not acted and when it has established a statutory minimum. Yet regulations cannot really be minima if the common law operates as a stopgap.

If the courts view regulatory standards as minima, there is no conflict with the statutory scheme if the agency itself has set a low standard in the belief that case-by-case adjudication is the best way to respond to the regulatory problem. Although this may sometimes be a plausible strategy, the plaintiff should bear the burden of demonstrating that the legislature intended it. Absent such a showing, a regulatory statute should be taken to imply a legislative judgment that a comprehensive, state-centered, *ex ante* approach is the best way to deter harm. The difficulties of judicial standard setting should lead judges to accept the stopgap role. If the regulations are indeed too lax, statutory or administrative reform is appropriate, not *ad hoc* judicial actions that respond to individual needs while producing systemwide inequities and inefficiencies.

Under the third form of complementarity, the doctrines of either negligence or strict liability can produce both a more consistent tort law and a more effective regulatory system. To accomplish this, however, courts must be prepared to surrender some of their independence in setting standards of care and assessing damages.

Consider a negligence rule that seeks to mimic the regulatory standard. In contrast to the asymmetric doctrine of negligence *per se*, the courts would also recognize a *per se* defense for injurers who meet the regulatory standard. The wrongdoer could thus be punished twice: by whatever sanctions the state imposes through the regulatory process, and by paying damages to private litigants. While this may seem unfair to the wrongdoer, it is not inefficient even if the sum of the penalties exceeds the social costs of violating the standards. Convicted wrongdoers would pay "too much," but anyone can avoid this overcharge by simply conforming to the regulatory requirements. This optimistic view is true, however, only if agencies set clear standards, courts accept these standards in determining liability, and apply them competently to individual cases.

Suppose now that the tort standard is not negligence but true strict liability, which holds a manufacturer liable for all harm caused by its product and only requires the court to determine causation, not to assess the risks and benefits of product design. True strict liability differs substantially from the "strict liability" of products law, which essentially requires the jury to make a negligence-like risk/utility calculation. Under true strict liability, torts and regulation need not conflict if damages are set equal to the harm caused by the tortfeasor. The possibility of a tort judgment will simply give the regulated entity an additional incentive to comply with the statute. The conditions assuring complementarity, however, do not now exist. To achieve them would require substantial tort reform, yet attempts to reshape tort doctrine according to its behavioral effects would be difficult.

In contrast to the complementary options outlined above, tort law can work at cross purposes to statutes when the regulatory standard is set at the socially optimal level of care, but the courts impose a more stringent negligence standard. Two cases need to be considered: compensatory damages and punitive damages.

Judges sometimes sharply distinguish the two, finding punitive damages "regulatory" but not compensatory damages (for example *Silkwood v. Kerr-McGee*, Powell dissenting, p. 276). Under this view, the goal of compensatory damages is merely to make the victim whole, not to induce behavioral changes in potential injurers; thus compensatory damages cannot conflict with a regulatory purpose. If tort actions only provided compensation and if the agency's own enforcement mechanisms effectively assured compliance with its standards, this view might be correct. But these assumptions are always false where no statute exists (the stopgap case) and are often false even when one does.

To see the judicial error, suppose that a regulatory agency has set a product standard at the optimal level, but courts nonetheless find that complying firms have been negligent or have defectively designed their product. A firm will then compare the extra costs of meeting the court's standard

with the damages it must pay victims if it merely complies with the lower regulatory agency standard. If it can increase profits by complying with the court's negligence standard, the firm will do so. At this care level, however, it will surpass the optimal agency standard, and marginal costs will exceed marginal benefits.

Judges who distinguish between compensatory and punitive damages, however, are not completely misguided. Punitive damages also influence caretaking and product design but may produce a different outcome than compensatory damages. If the courts impose a higher standard of care than is required by socially optimal statute, economic distortions will occur. The regulated firm subject to punitive damages will choose one of two options (depending upon which is profit maximizing): compliance with the tort standard where no damages are levied, or a level of safe design (somewhere between the socially optimal level and the tort standard) at which its marginal costs equal marginal punitive damages.¹

III. Regulatory Reform

Commentators have long urged legislators and regulatory agencies to charge fees set to reflect the risks created by regulated firms. Incentive-based reforms allocate regulatory costs to those who can bear them most efficiently, encourage firms to search for innovative ways to reduce harms, and force producers to reflect the risks they impose on society.

Such reforms, however, could be undermined by a poorly informed judiciary. If courts equate regulation with standard setting, then they may treat only command-and-control regulation as behaviorally significant. In a recent case, for example, the Superfund law was described as "not a regulatory standard-setting statute" because polluters pay for the cost of abating hazardous wastes "through tax and reimburse-

ment liability" (*State of New York v. Shore Realty*, 1985, p. 1041).

Incentive schemes require a fundamental rethinking of the relationship between tort law and statutory law. How should courts handle claims by defendants that incentive-based regulatory statutes preempt tort actions? Judges who view regulation as confined to standard setting might allow tort actions on the ground that these statutes are not "regulatory" because they do not establish uniform standards but "only" create incentives. Yet the argument for preemption of tort law is even stronger in the case of incentive-based regulations than in the case of command-and-control regulation. A well-designed incentive system signals to a firm the social costs of its activities. A fee system resembles a tort liability system: No fixed standards are set, but firms respond to the cost of damages. The regulated entity must purchase the right to impose social costs in the same way that a tort judgment requires payment for harms. The main difference is the comprehensiveness of a fee schedule, which the state sets so that all firms are covered. A firm's liability does not depend on the contingency of private litigation and jury damage awards.

If fee schedules are set to reflect the social costs of the regulated firm's activities, tort judgments would undermine the regulatory scheme, especially if courts applied a strict liability standard, the type of standard which some judges have found least "regulatory" (*Silkwood v. Kerr-McGee*, p. 276 n. 3). Thus incentive-based statutes should include a provision clearly preempting tort actions. The only role for lawsuits by private individuals would be to force the *agency* to enforce its own rules; such suits might permit private recovery of damages for harm caused by lax enforcement. Although ordinary tort actions would be preempted, certain specialized private remedies might supplement agency enforcement just as tort actions do which use regulatory standards as the standard of negligence.

IV. Compensation

Tort law provides more than a set of regulatory incentives; behavior modification

¹ Punitive damages may reflect not punishment of the tortfeasor but a correction for the fact that only a fraction of victims sue. If the courts set the damages multiplier to correct for this, the earlier analysis of compensatory damages applies.

is not its only legitimate function. It is also a compensation system triggered by victims' complaints. If a regulatory statute bars private tort actions, those who were previously able to sue for damages will be disadvantaged, a result courts seem reluctant to permit (*Silkwood v. Kerr-McGee*, p. 251). If compensation of victims is not addressed by a purely regulatory statute but remains a policy goal, courts may apply conventional tort doctrines that are at cross purposes with regulatory policies. Yet retaining conventional tort actions in the face of regulatory statutes can undermine the behavioral impact of statutes. Other solutions must be found to the problem of providing compensation.

If the victims are numerous and their losses fall into broad, easily identified categories, such as lost limbs or particular types of cancers, then the compensation goal could be served by direct subsidy programs like workers' compensation and the black lung program. In contrast, if the victims are few in number and their problems are idiosyncratic, the law should either permit private rights of action for damages analogous to those permitted under the Consumer Product Safety Act and the Comprehensive Environmental Response, Compensation and Liability Act (Superfund),² or it should allow tort actions under strict liability principles solely as a means of achieving compensation.

V. Conclusions

The tort system has shown itself inadequate to deal effectively with problems, such as latent cancer risks and attenuated chains of causation, which do not fit easily into

traditional tort categories. The innovations that the courts have developed to manage class actions and consolidate cases are transforming the courts into quasi-regulatory agencies. Real agencies are likely to perform better than awkward judicial hybrids that have many of the disadvantages of both forms.

Reform-minded policymakers should carefully reexamine the relationship between tort law and statutory regulation. The widespread presumption favoring a vigorous tort system should be replaced with a more comprehensive view of the alternative ways to achieve both deterrence and compensation. Privately initiated lawsuits, brought either under tort principles or under regulatory statutes, should be quite limited and targeted on augmenting regulatory enforcement and responding to unusual situations that would be poorly resolved by broad-based regulations.

²Under the CERCLA, private individuals can sue generators of hazardous wastes for cleanup costs (but not for personal injuries) even if the government has taken no action against the waste generator.

The Safety and Innovation Effects of U.S. Liability Law: The Evidence

By ROBERT E. LITAN*

Although it has vanished from the front pages, the "liability crisis" still continues to occupy the attention of policymakers, the business community, and consumers. Indeed, many states have responded to the crisis by enacting "tort reforms" to make it more difficult for accident victims to sue and, if they win, to recover large awards.

Manufacturers and insurers have supported these efforts because they believe that the tort system has become so expensive and uncertain that is "overdetering," discouraging the production of valuable products and the innovation of many more. Plaintiffs' lawyers and consumers groups vigorously disagree, arguing that current liability law provides important incentives for private actors to make safer products and to conduct their activities in a less risky fashion.

Given the significant impacts of the tort system (by one recent estimate, gross liability expenditures in the United States amounted to \$117 billion in 1987, see Tillinghast, 1989), it is somewhat surprising that there is so little empirical research to settle this debate.

In fact, there even is a lack of consensus on liability trends. Although there are no comprehensive nationwide data on the numbers of nonautomobile tort suits, verdicts, and settlements, by all available measures, total liability costs (primarily insurance premiums, but also estimates of self-insurance payouts) have been rising during the last 30 years, and especially rapidly in the 1980's (U.S. Department of Justice, 1986; Mark Peterson; 1987).

In 1989, the Brookings Institution launched a major study designed to determine the "safety" and "innovation" impacts of this expansion in the tort system on five sectors of the U.S. economy; the private aircraft, automobile, chemical and pharmaceutical industries, and the medical profession. As project directors, Peter Huber and I commissioned experts to address each side of the debate for each of these sectors, deliberately seeking individuals who were *not* economists. As discussed below, it is extremely difficult (some would say impossible) to establish through standard econometric techniques the linkages, if any, between liability law and safety and/or innovation. Accordingly, we believed the project could shed more light on the subject by engaging individuals with scientific or practical backgrounds in the specific sectors they were asked to study; in a few cases, economists met these criteria and they participated. This article summarizes some of the key findings from this effort (1991).

I. A Brief Review of the Preexisting Literature

The "evidence" that liability has had a "safety-enhancing" effect is largely anecdotal. Recent books and articles, for example, have pointed to specific substances and devices that allegedly or actually have led to mass harms (Agent Orange, the Dalkon Shield contraceptive, asbestos, and tampons) and subsequently have been removed from the marketplace in the aftermath of tort litigation. In addition, there are many other accounts of unsafe products or practices that have been attacked, successfully or otherwise, in court, but it is often difficult to determine from these accounts whether tort verdicts were the reason for the remedial actions that supposedly followed the litigation, or alternatively that these remedies cured real problems. Similarly, while

*Senior Fellow and Director, Center for Economic Progress and Employment, Economic Studies Program, The Brookings Institution, 1775 Massachusetts Avenue NW, Washington, D.C. 20036.

George Eads and Peter Reuter (1983) find from their interviews of corporate managers that product liability exerts a strong "pro-safety" effect on product design, they also confess that current liability law sends an "extremely vague signal" since it does not indicate "*how* to be careful, or more important, *how* careful to be" (pp. viii-ix).

Statistical analysis of the safety effects is rarer, but the little that exists reports little impact. Thus, George Priest (1989) finds that while the annual numbers of tort suits and aggregate liability insurance premiums rose sharply during the 1980's, injury rates for consumers and workers, death rates from medical procedures, and aviation accident rates showed no more rapid a decline in that decade than in the 1970's when the volumes of tort suits and premium costs were far lower. Obviously, a demonstration of this sort does not distinguish the contributions that other factors (notably, consumer demand for safety and/or preventative measures taken by consumers, and regulation) might have made to the declining injury and death rates. But Priest's work nevertheless raises doubts that the safety benefits from expanded liability have been large.

The literature on the innovation side of the debate also has been relatively sparse, and to some extent contradictory. The Conference Board, for example, has put out two studies with conflicting conclusions: an early survey of corporate risk managers who report relatively little harmful effect of liability (E. Patrick McGuire, 1988) and a follow-up survey of chief executive officers who report much more substantial negative effects (Nathan Weber, 1989). There are also anecdotes of arguably socially useful products and services (principally medical) withdrawn from the market allegedly because of the uncertainty created by the liability climate.

Economists will have a hard time (to put it mildly) using traditional statistical methods sorting out the conflicting claims about tort law's impacts in a convincing fashion. First, it is difficult to specify and/or gather data on the appropriate dependent variable. Although safety is relatively easy to mea-

sure (by such variables as injury and death rates), objections may be lodged against all of the standard measures of innovation: by inputs (such as R&D expenditures) or outputs (such as the numbers of patents or new products introduced).

Second, and more troubling, is the difficulty of specifying and obtaining adequate data representing the influence of liability. As noted earlier, there are no comprehensive time-series data for a sufficient period of time to perform meaningful statistical analysis on the total numbers of tort suits (in both federal and state courts combined), favorable verdicts and/or settlements, or dollars paid through or on account of the liability system, especially by industry.

Third, any worthwhile statistical analysis of liability's impact must account for the influence of other important variables—perhaps, most importantly, regulation. Yet how does one reliably measure regulatory intensity? Proxies such as the numbers of regulatory personnel and dollars spent by the agencies that employ them ignore important distinctions between the way regulation is implemented (through performance standards or design controls, for example) and thus may not capture regulation's true effects.

Notwithstanding these difficulties, it may still be possible to make rough estimates of liability's effects during the limited time periods for which data are available. But with the relevant statistical data so thin, it is useful in the meantime to collect information through other means.

II. Safety Impact¹

Most of the authors who addressed the safety side of the liability debate found little direct or statistical evidence that specific liability verdicts have led to substantially safer products. To be sure, tort suits often induce manufacturers to expand or modify warnings, but there also is little concrete

¹Authors cited in Sections II and III can be found in my 1991 study with Huber.

evidence that such redesigned warnings have resulted in fewer deaths and injuries.

This does not mean that the authors found that liability has no safety effects at all. Instead, there is evidence that tort law has a safety-enhancing impact that works *indirectly* through the adverse publicity that tort suits, and more importantly, proplaintiff verdicts generate about particular products. Thus, for example, John Graham demonstrates that liability verdicts involving the Ford Pinto and the "CJ" Jeep led to negative press stories (especially on national television) that in turn diminished consumer demand for these vehicles.

But when it comes to product design, our authors for the most part concluded that the most important impulses for safety come from *outside* the liability system: through a combination of consumer demand for safety, standards for professional liability (in the case of medical services), and regulation (especially in the case of automobiles, pharmaceuticals and private aircraft). For products with long lives (such as aircraft and even cars) this is not surprising. Product litigation in such cases often arrives years after designs have changed for market-driven reasons or in response to prodding by regulators.

Our authors also found evidence supporting the view expressed by Eads and Reuter that the liability system sends confusing signals to private actors, in significant part because courts and regulators often have reached markedly different conclusions about how accidents are caused. This, too, would help account for the weak effects of liability on safer design.

Louis Lasagna, for example, points to the dramatic differences between the favorable analysis and pronouncements of the Food and Drug Administration on the dangers of Benedictin (a drug for preventing nausea associated with pregnancy) and various vaccines, and the far more negative verdicts on the same products rendered by the legal system. Similarly, Robert Martin describes a sharp divergence between the postaccident findings of the National Transportation Safety Board and the Federal Aviation Administration (which during the sample pe-

riod he analyzed found that design or manufacturing defects accounted for *none* of the more than 200 accidents) and the many lawsuits filed in connection with the same accidents claiming that defects were the sole cause of the mishaps. Finally, Stanley Reiser suggests that because few doctors believe the liability system produces accurate results, doctors have altered their practices in ways that are far more costly (due to the practice of "defensive medicine") and potentially less conducive to patient welfare (due to the erosion of trust formerly inherent in the doctor-patient relationship).

Indeed, several of our authors maintained that the threat of product liability can *deter* safety improvements. One automobile manufacturer feared making design changes that could easily be interpreted by juries as an admission that the prior design was defective. In one area where changes *were* made (the decision by automobile manufacturers to phase out tension relievers in seat belts, in part for liability reasons), Graham points out that the replacement "slack" seatbelts are less safe than their predecessor. Similarly, Martin found that in comparison to the prior decades when liability litigation was not that pervasive in the aircraft industry, the rate of decline in the aircraft accident rate *slowed* during the 1970-90 period when tort litigation was much more intensive. From this, Martin concluded that recent liability trends actually may have retarded the introduction of safer designs (although Martin's statistical analysis did not control for other factors that may have affected trends in aircraft accident rates).

A key exception to these relatively negative verdicts on the safety impacts of the current tort system is a paper by Nicholas Ashford and Robert Stone, which argues that at least in the chemical industry (and perhaps elsewhere), liability law *underdet*ers. Ashford and Stone contend this is largely because it is extremely difficult for juries and courts to link specific chemical agents with particular adverse health outcomes (except for such "signature" diseases as asbestosis and mesothelioma in the case of asbestos, for example). In addition, the victims of harmful chemicals are often

workers, whose compensation for noneconomic damages is strictly limited by workmen's compensation laws.

Yet even Ashford and Stone must concede that workers can still file tort claims against the *manufacturers* of harmful substances and in this way circumvent the restrictions of workmen's compensation, which of course, is exactly what asbestos victims have done. Meanwhile, while it may be true *ex post* that liability may underdeter where science has not yet established cause-and-effect relationships between particular substances and human health, this does not mean that *ex ante* liability fails to deter. To carry the weight of their argument, Ashford and Stone must demonstrate that juries and courts consistently ignore causal linkages that the scientific community has already demonstrated. While they present suggestive evidence that the risks of certain chemicals *may* be more dangerous than certain government agencies and courts have admitted, it is this author's view that the jury is still out on these claims.

III. Innovation Impact

Unlike the attempts to determine the safety impact of liability, which at least in principle involve observable events (a verdict and subsequent action), efforts to isolate the effect of tort law on innovation must uncover the proverbial "dogs that don't bark," or events that *do not* happen. Given the difficulty of this challenge, the Brookings researchers generally drew inferences from liability-related events that have occurred, much like physicists who infer the existence of subatomic events from the "traces" such particles leave behind.

Thus, Martin makes the case that the combined effects of uncertainty and high awards and settlements have largely decimated the private aircraft industry (where annual production levels have fallen by more than 80 percent from pre-1970's peaks), while contributing to the declining rate of introduction of new light aircraft. He estimates that liability costs added an average of \$70,000–\$100,000 to the costs of private airplanes built in 1987.

Lasagna finds that liability has discouraged research into certain types of pharmaceuticals and vaccines (especially those that could benefit children and pregnant women).

Murray MacKay argues that fears of liability help account for the fact that in recent decades European auto manufacturers have been the first to introduce, or to have researched more aggressively, a number of new safety-enhancing technologies relating both to crashworthy structures and occupant protection (primarily seat belts but more recently side-impact airbags). In addition, McKay provides evidence that liability concerns played a role in the opposition by U.S. auto companies to regulatory efforts to mandate airbags.

Finally, Kip Viscusi and Michael Moore supplemented the anecdotal and historical evidence with a cross-sectional statistical analysis of the innovation effects of recent liability trends. They measured liability by annual insurance losses experienced in various sectors of the economy during the 1980–84 period, or the years in which the "liability crisis" of the 1980's first manifested itself. Innovation was proxied both by R&D costs and a measure of new products introduced. In brief, they found that for industries with relatively low liability costs, the liability system appeared, if anything, to encourage innovation—a result consistent with the theoretical arguments that liability will induce efforts by private actors to take greater precautions. But for industries such as private aircraft, where liability costs rose substantially during the 1980's and represented significant shares of total costs, liability appears to have dampened innovation.

IV. Policy Implementation

At the risk of oversimplification, the evidence compiled by the Brookings project at the very least raises significant questions about the magnitude of the "safety benefits" of the current liability system, while also providing circumstantial evidence that in certain industries its deleterious effects on innovation may be substantial. In a perfect world, therefore, one would like to scale

back its impact in just those sectors of the economy where the costs seem to outweigh the benefits.

But the U.S. legal system does not permit such precision; legal rules adopted for one industry tend, with few exceptions, to be applicable to all. Given the continued shortage of decisive empirical information, what should be done?

First, liability (as does regulation) attempts to induce safety-enhancing behavior by punishing or curtailing the activities of firms and individuals. Since this *negative* approach has at best ambiguous net benefits, it would be desirable for tort law to develop *positive* incentives for safety. Along these lines, judges and legislators might consider allowing manufacturers who demonstrate that they promptly correct design defects, or have active programs under way, to experiment with safety innovations at least some exemption from liability claims. Similar incentives should be applied for those who comply with applicable regulatory standards in a timely fashion.

Second, many of our authors pointed to the uncertainty generated by the liability system as one of its major vices. Although much of the uncertainty is due to nondoctrinal matters (differences in judges and juries, for example), one doctrinal change yet to be adopted in many jurisdictions is a "statute of repose" that would effectively immunize products from liability if they have been on the market for a lengthy period (say 10 years) without a successful tort challenge.

Third, rules of evidence in tort cases should make it possible for judges and juries to give more consideration to the broader *social* benefits of products and services at issue in tort cases, especially those at the technological frontier. The cutting-edge new drug or surgical procedure may offer many gravely ill patients a chance of recovery that cannot be found elsewhere; society at large may benefit from such technological advances even if a specific plaintiff may not. Legal rules, jury instructions, and evidential standards should thus be drafted to give more weight to the actual and potential benefits of innovations so as not to deter them with negative liability judgments.

This last point highlights the fact much of the impact of the current U.S. tort system is felt not through specific doctrines but through a variety of ancillary factors that have provided strong incentives to injured parties to use our tort law as a device for obtaining compensation far more intensively than victims in other industrialized countries. As Gary Schwartz points out in his contribution, there are surprisingly few doctrinal differences in the tort law of the United States, Europe, and Japan: all countries use a negligence standard for medical practice and "strict liability" for product design defects (which, in practice, are tried under a negligence-type standard that involves the weighing of risks against benefits). Instead, what makes the United States so different is the far greater numbers of tort actions, and the damage awards and settlements the successful suits produce. Several factors, mostly outside the narrow field of tort law, are responsible: the use of juries to decide cases, but far less frequently (or not at all) abroad; the American system of contingent attorneys' fees (present in Japan, but not in England where in fact losing parties pay the winner's lawyers fees); the more liberal rules allowing plaintiffs to recover damages for pain and suffering (the one tort-specific doctrine that may be important); and more liberal discovery rules in the United States for all types of litigation. The importance of these nontort factors, which are difficult if not impossible to change, provides a strong caution to those who believe that just by modifying certain tort doctrines, the net benefits of the overall system can be significantly enlarged.

Mispriced Equity: Regulated Rates for Auto Insurance in Massachusetts

By B. GLENN BLACKMON, JR. AND RICHARD ZECKHAUSER*

From the Santa Monica Freeway to the New Jersey Turnpike, drivers are unhappy about the cost of automobile insurance and are asking government to do something about it. California voters approved Proposition 103 in 1988; it requires that all rates be approved by the state insurance commissioner, attempts to reduce rates by 20 percent, and dramatically limits the criteria that can be used to rate drivers for premium purposes. New Jersey enacted an insurance reform law that seeks to charge insurers for a deficit-burdened state underwriting pool and prohibits the use of age, sex, and marital status in rating drivers for premiums. Other states enacting or considering significant rate rollbacks or reform since 1988 include Arizona, Florida, Michigan, Nevada, and Pennsylvania.

This article describes the current consequences of similar policies adopted in Massachusetts more than a decade ago. The experience suggests that recent moves by other states in the same direction will ultimately prove quite expensive as the proportion of high-cost drivers increases and as insurers lose the incentive to write policies and control costs. The trend away from insurance premiums based on expected cost also reduces incentive effects for drivers, since insurance premiums provide a link between tort judgments and consumer decisions.

I. Insurance Regulation in Massachusetts

The insurance commissioner in Massachusetts specifies a rating system for classifying drivers and sets a single schedule of

rates that apply to any insurer in the state. The state eliminated sex-based rate differences for automobile insurance in 1977, when the state insurance commissioner concluded that "sex classifications in automobile insurance represent unfair discrimination. Rates containing a distinction based on gender are both unjust and violative of public policy" (James Stone, 1978, p. 179). At the same time, rate differences based on age were also eliminated and replaced with rating classes based on the number of years as a licensed driver. The state classification system allows rates to vary by territory (i.e., the place of residence of the driver), class (i.e., whether an inexperienced driver is the principal or an occasional driver of the car, whether any inexperienced driver has had driver training, and whether the car is used for business), and the age and type of car.

The state has "tempered" (limited the variation of) premiums across territories and classes. Across classes, the expected cost of insuring a driver varies by a factor of 4.4, but premiums vary by a factor of 3. Across territories, costs vary by 2.7 and premiums by 2. When class and territory are combined, the effect of tempering is even greater. The premium for drivers in the highest class-territory cell is 4.50 times the premium of the driver in the lowest cell, yet the cost of insuring the high-cell driver is 10.6 times the cost of insuring the low-cell driver (Automobile Insurers Bureau, 1990, exhibit 5).

In addition to the transfers among drivers, insurance regulators have also apparently tried to effect a transfer from insurers to drivers as a group. The insurance industry contends that overall rates are consistently below the level necessary to provide a profit. This claim would be expected from the industry as strategic behavior in the rate-setting process, and it would have little credibility if insurers were continuing to do

business in the state. Yet by 1989, eight insurance companies, writing 25 percent of automobile coverage in the state, had abandoned business in Massachusetts or were actively attempting to do so, despite high exit fees imposed by the insurance commissioner. These exit fees include both cash payments and prohibitions on writing other lines of insurance in the state.

While an insurance company is allowed no flexibility in the rates it charges, it can choose whether to insure a particular risk. Many companies choose not to insure many drivers. If an insurer declines to insure an exposure, that driver is ceded to a residual market pool, Commonwealth Auto Reinsurers (CAR). Being ceded to the pool has no effect on the driver's premium, and as a result the residual market pool pays claims well in excess of premiums. In 1988, 63 percent of drivers were insured by CAR, and the CAR deficit for private passenger automobile insurance was \$519 million, or \$239 per ceded risk (Commonwealth Automobile Reinsurers, 1988). This residual market deficit is financed by surcharging premiums for drivers in the voluntary market.

II. Subsidies in Massachusetts Auto Insurance Rates

The subsidies contained in Massachusetts auto insurance rates are large and multidimensional. Subsidies flow from drivers in rural areas to those in urban areas, from women to men, from the middle-aged to the young and the elderly, from experienced drivers to inexperienced drivers, and from drivers in the voluntary market to those in the high-risk, involuntary market.

How large is the subsidy? A minimum value would be the size of the residual market deficit (\$519 million), but the true value is surely larger since some ceded drivers are actually paying more than their cost. About \$191 million results from the tempering of rates across class/territory cells. The remainder, at least \$328 million, can be attributed to the state rating system that requires insurers to charge a single premium

TABLE 1—AVERAGE SUBSIDY AND PRICE OF THOSE PAYING AND RECEIVING SUBSIDIES

	Average Cost	Insured Vehicles (000)	Average Premium	Subsidy
<i>s</i>	\$1,312	820	\$1,079	\$233
<i>c</i>	\$928	1,251	\$665	\$262
<i>n</i>	\$323	1,216	\$750	(\$427)

Note: *s* = subsidized cell; *c* = ceded to residual market; *n* = not ceded or subsidized.

to a heterogeneous group of drivers. A cell that, on average, is charged premiums in excess of cost will nonetheless contain some drivers whose costs exceed the premium. Many of these drivers can be readily identified by an insurer and are ceded to the residual pool. For example, the average experienced driver 25 or older pays a subsidy of about \$60 per year, yet 60 percent of these drivers are ceded to the residual market. Recognizing this, we divide drivers into three groups in Table 1: those in a cell that receives a subsidy through tempering (*s*); those in a subsidy-paying cell but who receive a subsidy from ceding (*c*); and those neither tempered nor ceded (*n*). The first two groups receive a subsidy, and the third group pays a subsidy. We assume that all drivers in a subsidy-receiving cell are ceded and that the proportion of ceded drivers is constant across subsidy-paying cells.

These subsidies generate allocative inefficiency: those who pay the subsidies restrict their consumption of automobile insurance, by not driving or by driving without insurance. Those receiving the subsidies increase their consumption. A deadweight loss results as some consumers are deterred from driving even though they would pay the cost and others drive when they would not if prices reflected costs. To assess the deadweight loss from the subsidies, we first estimated a simple demand function for insurance using data from Massachusetts towns in 1988. The demand for insured vehicles per household was estimated as a log-linear

(constant-elasticity) function of income, price, and household density.¹

Using this demand function, we calculated deadweight loss from the subsidies at \$217 million annually, or 42 percent of the total subsidy. (This 42 percent figure seems high until we recognize that if the cross-subsidy scheme must break even, the losses of both those undercharged and overcharged must be counted.)² The deadweight loss is substantial, but it alone does not tell us whether the policy of subsidies is good or bad. There are at least two possible rationales for subsidies—risk spreading and egalitarianism.

Subsidies as a risk-spreading mechanism. The state's rationale for subsidizing high-cost drivers at the expense of low-cost drivers (as explained by the commissioner) in essence is to spread the risk that one may be a bad driver (Stone). If drivers were risk averse and did not yet know whether they are high- or low-cost drivers, they could increase their expected utility by agreeing to

pay more than cost if they are low-cost and less than cost otherwise. How risk averse would Massachusetts drivers have to be for the observed pattern of tempering to be superior to cost-based prices? To answer this question, we first computed the gain from driving, g , as the per capita consumers' surplus up to the \$5,000 available at the bottom of the demand curve. We then posited household utility, U , as a function of money income, y , plus the gain g derived from operating an insured vehicle. For each cell of individuals, i , let $x_i = y_i + g_i$. We express utility as a constant proportional risk-aversion function, $U_i = u(x_i) = x_i^b$, where b is a risk-aversion parameter to be estimated. We measure the effect of the subsidies by their effect on the expected utility of a randomly chosen individual, one who knows only the proportions of individuals who will be subsidized and by how much but not his particular group. The relevant individuals are those who would own a car under either the subsidized rates or cost-based rates. (There would be 1.993 million drivers in group n if rates were based on cost.)

For any given set of prices, the expected utility $E(U)$ is equal to the utility of an individual in each group, weighted by the proportion of individuals (potential drivers) in that group. Each of the three groups in Table 1 is divided into finer units based on class and territory, yielding a total 1,092 cells. Thus

$$E(U) = \sum_{i=1}^{1,092} [d_i * (30,000 + g_i)^b],$$

where d_i is the proportion of individuals in cell i and all drivers are assumed to have household income of \$30,000. We find the highest value for b at which $E(U)$ under the current subsidy regime is equal to $E(U)$ under a regime in which each group was charged a price equal to its expected cost. For the subsidized outcome to offer at least as high an expected utility, b must be less than or equal to -7.2 . At this level of risk aversion, an individual's marginal utility of

¹Our illustrative estimation applies ordinary least squares to data from 294 towns. Our right-hand side variables were median household income in 1979 (the latest year of town-level data), average price of a standard package of insurance coverage, and households per square mile as the density measure. The demand for vehicles should decrease with population density because substitute transportation becomes more readily available. Thus, we expect the coefficients on income to be greater than zero, and on price and density to be less than zero. Our estimated coefficients, with standard errors in parentheses, were income .477 (.044), price $-.569$ (.119), and density $-.044$ (.011). Our R^2 was .593. All coefficients are significantly different from zero at the 99 percent confidence level (see our 1990 paper). We did not have a sufficiently rich data set to control for exogenous variables that could influence the driving decision. In contrast to a traditional market, supply conditions were favorable for our estimation efforts, since all prices were set by regulators, and the supply curve for each cell was horizontal (any driver had to be accommodated at the established rates).

²Our measure of deadweight loss does not include the inefficiency from pricing at average cost instead of marginal cost. Using data on insurance costs, we estimate that marginal cost exceeds average cost by 40–60 percent in urban areas of Massachusetts. The additional deadweight loss is \$81 million (see our 1990 paper).

income drops by an implausible factor of 295 as his income increases from \$15,000 to \$30,000.

Subsidies as an income transfer mechanism. A second rationale for subsidies would be to transfer income from consumers with high income to those with low income, again as a way of raising the expected utility of a randomly selected consumer (i.e., egalitarianism in the spirit of an optimal income tax trading off incentive losses against risk-spreading gains). Tempering a commodity price, such as an auto insurance premium, can accomplish this purpose only if high-cost consumers tend to have low incomes. The relationship between subsidies and income is decidedly mixed in the case of automobile insurance. The subsidy of Boston and other cities tends to flow from high-income towns to low-income towns. Yet women subsidize men even though women's income is much lower. In many cases the group paying or receiving a subsidy is simply too diverse for us to estimate its income.

Measuring only variations across towns, we estimate that the average household income of group *s*, those in a cell receiving a tempering subsidy, is \$26,500, measured in 1988 dollars. Since the drivers in group *c* and group *n* are in the same cells, their average income is the same, \$30,418. Given these assumptions about income, an egalitarian motive justifies the subsidies if $b < -2.7$. At this level of risk aversion/egalitarianism, the marginal utility of income at \$15,000 is 13 times that at \$30,000. (For this utility function, taking account of variability in incomes within cells would increase the relative attractiveness of the subsidy scheme.)

We have not attempted to measure the egalitarian sentiment of Massachusetts citizens, but a look at the state's social programs and tax system suggests that it is not nearly this strong. Moreover, this redistributive bucket is extraordinarily leaky; other instruments, such as taxes and transfers, could effect the transfer with significantly smaller losses.

"Price equity" as a goal. Neither risk aversion nor egalitarianism, if their implicit

tradeoff rates are examined, yields a satisfactory justification for the subsidies in Massachusetts auto insurance rates. We believe that the subsidies may be better explained (though not justified) by a desire for price equity, the idea that differences in price for goods that are nominally similar is in itself a bad thing. Price equity is a sensible goal, and a natural accompaniment of competitive markets, when the cost of the product does not depend on who consumes it. Variation in prices across a market is usually welfare reducing, but not for insurance. The expected cost of insurance varies in predictable fashion for large subsets of consumers, though not for any particular consumer.

Even a well-informed consumer, however, would find it difficult to judge the absolute or relative cost of his coverage and would probably underestimate variation in cost across insureds. With little idea about cost, consumers judge their rate relative to others—both rates charged other consumers and the rates they paid in the past. If consumers assess the fairness of rates on a relative scale, a politically responsive regulator would set rates on the same basis.

The recent insurance reforms in California and New Jersey significantly temper rates, promoting the notion that significant variation in rates across consumers is unfair. The demand for price equity is reflected in prices for electricity and natural gas (typically the same for rural and urban customers of the same company despite cost differentials), tuitions for college students (invariant across fields with disparate costs of facilities and faculty), and the invariant cost of sending a letter.

III. Regulation and the Residual Market

A heavily subsidized market has important and negative effects on the incentives of insurers. These effects are most apparent in the operation of the residual or involuntary market, which was intended to be a last-resort insurance source for high-risk drivers. It now insures more than two-thirds of Massachusetts drivers, its size the inevitable consequence of that state's strategy

of limiting absolute rates and tempering relative rates.

Every state provides some mechanism to insure drivers who cannot obtain insurance at standard rates. The most common mechanism, used in about 40 states, is the assigned-risk plan: drivers who cannot obtain insurance are assigned to an insurer, who is responsible for all expenses and losses of that policy. Massachusetts uses a reinsurance mechanism. Drivers are not assigned to a specific insurer; rather their losses are allocated among insurers. Massachusetts is unique in requiring that residual and voluntary market drivers in the same rating category pay the same rate. Tempering and heterogeneous classifications both increase the ceding of risks, and Massachusetts now has more drivers in the involuntary market (70 percent of all drivers in 1989) than any other state (Timothy Gailey, 1989, p. 5). Since 1977, when the state adopted its policy of tempering rates and prohibiting sex- and age-based rates, the total number of insured drivers has increased by 35 percent. However, the number of drivers voluntarily covered by insurance companies has decreased by 35 percent.

The high proportion of drivers in the residual pool undermines the incentive of insurers to minimize cost; for instance, by limiting fraudulent claims and excessive payments for repairs. Most claims are paid from the residual pool, where all insurers share the loss. Thus an individual insurer will bear all of the cost and almost none of the benefit from greater efforts to control the cost of these claims.

IV. The Implication for Torts

The systematic mispricing of automobile insurance in Massachusetts, and the trend toward the Massachusetts method in other

states, undermines the rationale for preserving some element of a tort liability system. When insurance is priced at cost, the premium reflects the tort claims that can be expected if the consumer engages in the insured activity, and the consumer will make an efficient decision about whether to operate a motor vehicle, though his incentive to drive safely will be insufficient.

V. Conclusion

Massachusetts suffers from significant deadweight efficiency losses, hence high prices, because regulated rates for auto insurance deviate substantially from cost. Taking an expected utility approach, for reasonable parameter values neither risk-spreading nor egalitarian concerns justify this cross-subsidy scheme.

PATH DEPENDENCE IN ECONOMICS: THE INVISIBLE HAND IN THE GRIP OF THE PAST[†]

Multiple Equilibria and Persistence in Aggregate Fluctuations

By STEVEN N. DURLAUF*

Recent developments in theoretical macroeconomics have emphasized the potential for multiple, Pareto-rankable equilibria to exist for economies where various Arrow-Debreu assumptions are violated. Authors such as Peter Diamond (1982) emphasized how incomplete markets can allow economies to become trapped in Pareto-inferior equilibria; Walter Heller (1986) obtained similar results due to imperfect competition. These different approaches share the idea that strong complementarities in behavior can lead to multiplicity. Intuitively, when technological or demand spillovers make agents sufficiently interdependent, high and low levels of activity can represent internally consistent equilibria in the absence of complete, competitive markets. Most of these models describe multiple steady states in economies rather than multiple nondegenerate time-series paths, and consequently cannot address issues of aggregate fluctuations. Further, this literature has not shown how economies can shift across equilibria, inducing periods of boom and depression.

An independent literature has argued that aggregate fluctuations are strongly persistent. Researchers have concluded from a variety of perspectives that aggregate output in advanced industrialized economies con-

tains a unit root. Despite controversy over the exact magnitude of the permanent component, the effects of current events on real activity apparently persist over long horizons.

The purpose of the current paper is to link the new multiplicity results in macroeconomic theory with the evidence on output persistence. I do this by modeling coordination problems in an explicitly stochastic framework. As developed in my earlier papers (1990; 1991), the microeconomic specification of the economy is expressed as a set of conditional probability measures describing how individual agents behave given the economy's history. An aggregate equilibrium exists when one can find a joint probability measure over all agents which is consistent with these conditional measures; multiplicity occurs when several such measures exist. This approach permits one to directly describe the time-series properties of aggregate fluctuations along different equilibrium paths.

Specifically, I examine the capital accumulation problems of a set of infinitely lived industries. I deviate from standard analyses in two respects. First, each industry faces a nonconvex production technology. Second, industries experience technological complementarities as past high production decisions by each industry increase the current productivity of several industries through dynamic learning by doing or other effects. Industries do not coordinate production decisions because of incomplete markets. By describing how output levels and productivity evolve as industries interact over time, the model characterizes the impact of complementarities and incomplete markets on the structure of aggregate fluctuations.

I. A Model of Interacting Industries

Consider a countable infinity of industries indexed by i .¹ Each industry consists of many small, identical firms. All firms produce a homogeneous good; industries are distinguished by distinct production functions rather than distinct outputs. The homogeneous final good may be consumed by the owners of the firms, or converted to a capital good that fully depreciates after one period. Industry i 's behavior is proportional to the behavior of a representative firm that chooses a capital stock sequence $\{K_{i,t}\}$ to maximize the present discounted value of profits $\Pi_{i,t}$

$$(1) \quad \Pi_{i,t} = E \left(\sum_{j=0}^{\infty} \beta^j (Y_{i,t+j} - K_{i,t+j}) | \mathfrak{F}_t \right),$$

where $Y_{i,t}$ equals the output of the i th industry's representative firm at t ; \mathfrak{F}_t equals all available information at t . Initial endowments $Y_{i,0}$ provide starting capital.

Aggregate behavior is determined by the interactions of many heterogeneous industries employing nonconvex technologies. Production occurs with a one-period lag; firms at $t-1$ employ one of two production techniques and a level of capital to determine output at t . Only one technique may be used at a time. Russell Cooper (1987) and Kevin Murphy et al. (1989) exploit similar technologies to analyze multiple equilibria; Paul Milgrom and John Roberts (1990) discuss how this type of nonconvexity can arise as firms internally coordinate many complementary activities. The technique-specific production functions produce $Y_{1,i,t}$ and $Y_{2,i,t}$ through

$$(2) \quad Y_{1,i,t} = f_1(K_{i,t-1} - F_i, \zeta_{i,t-1}, \xi_{t-1})$$

$$Y_{2,i,t} = f_2(K_{i,t-1}, \eta_{i,t-1}, \xi_{t-1}).$$

$\zeta_{i,t}$ and $\eta_{i,t}$ are industry-specific productivity shocks; ξ_t is an aggregate productivity

shock and F_i is a fixed overhead capital cost; $\zeta_{i,t-1}$, $\eta_{i,t-1}$, and ξ_{t-1} are elements of \mathfrak{F}_{t-1} . Recalling that firms within an industry are identical, let us define $\omega_{i,t}$ which equals 1 if technique 1 is used by industry i at t , 0 otherwise and $\omega_t = \{\dots \omega_{i-1,t}, \omega_{i,t}, \omega_{i+1,t}, \dots\}$ which equals the joint set of techniques employed at t .

I make the following assumptions. First, each technique fulfills standard curvature conditions. Further, I associate technique 1 with high production. Specifically, net capital $NK_{i,t}$, that equals $K_{i,t} - F_i$ for technique 1 and $K_{i,t}$ for technique 2, has a strictly higher marginal (and by implication total) product when used with technique 1 than technique 2. A firm chooses technique 1 if it is willing to pay fixed capital costs in exchange for higher output.

ASSUMPTION 1: Restrictions on technique-specific production functions.

For all realizations of $\zeta_{i,t}$, $\eta_{i,t}$, and NK ,

- A. $f_1(0, \zeta_{i,t}, \xi_t) = f_2(0, \eta_{i,t}, \xi_t) = 0$.
- B. $\frac{\partial f_1(0, \zeta_{i,t}, \xi_t)}{\partial NK} = \frac{\partial f_2(0, \eta_{i,t}, \xi_t)}{\partial NK} = \infty$;
 $\frac{\partial f_1(\infty, \zeta_{i,t}, \xi_t)}{\partial NK} = \frac{\partial f_2(\infty, \eta_{i,t}, \xi_t)}{\partial NK} = 0$.
- C. $\frac{\partial f_1(NK, \zeta_{i,t}, \xi_t)}{\partial NK} > \frac{\partial f_2(NK, \eta_{i,t}, \xi_t)}{\partial NK}$.

Both techniques are assumed to exhibit technological complementarities, as the history of realized activity determines the parameters of the production function at t . Paul Romer's (1986) model of social increasing returns shares this feature. My complementarities differ from Romer's in two respects. First, all complementarities are local as the production function of each firm is affected by the production decisions of a finite number of industries. The index i orders industries by similarity in technology; spillovers occur only between similar technologies. Paul David (1988) describes the historical importance of local complemen-

¹My 1990 paper derives a general equilibrium version of this economy.

tarities in the evolution of technical innovations. Second, my complementarities are explicitly dynamic. Past production decisions affect current productivity, which captures the idea of learning by doing.

Specifically, I model the complementarities through the dependence of the productivity shocks $\zeta_{i,t}$ and $\eta_{i,t}$ on the history of technique choices (see my 1990 paper for a justification). Complementarities are assumed to be the only source of dependence across shocks. $\text{Prob}(x|y)$ denotes the conditional probability measure of x given information y ; $x(y)$ denotes the random variable associated with this measure. $\Delta_{k,l} = \{i - k \dots i \dots i + l\}$ indexes the industries that affect industry i 's productivity.

ASSUMPTION 2: Conditional probability structure of productivity shocks.

A. $\text{Prob}(\zeta_{i,t}|\mathfrak{F}_{t-1})$

$$= \text{Prob}(\zeta_{i,t}|\omega_{j,t-1} \forall j \in \Delta_{k,l}).$$

B. $\text{Prob}(\eta_{i,t}|\mathfrak{F}_{t-1})$

$$= \text{Prob}(\eta_{i,t}|\omega_{j,t-1} \forall j \in \Delta_{k,l}).$$

C. The random pairs $(\zeta_{i,t} - \zeta_{i,t}(\mathfrak{F}_{t-1}), \eta_{i,t} - \eta_{i,t}(\mathfrak{F}_{t-1}))$ are mutually independent of each other and of $\xi_i - \xi_i(\mathfrak{F}_{t-1}) \forall i$.

No markets exist whereby individual firms can coordinate to exploit complementarities. Consequently, no industry may be compensated for choosing technique 1 in order to expand the production sets of other industries; nor, given my conceptualization of industries as aggregates of many small producers, can firms within an industry strategically choose a technique in order to induce higher future productivity through complementarities. Market incompleteness combines with the production nonconvexity to fundamentally affect aggregate dynamics.

II. Local Complementarities and Multiple Equilibria

I initially analyze the economy without aggregate shocks, by setting $\xi_i = 0 \forall i$. From my assumptions, one may show that equilib-

rium industry technique choices obey conditional probabilities of the form

$$(3) \quad \text{Prob}(\omega_{i,t}|\mathfrak{F}_{t-1}) \\ = \text{Prob}(\omega_{i,t}|\omega_{j,t-1} \forall j \in \Delta_{k,l}).$$

Once technique choices are determined, one can solve for the optimal levels of capital and output for each firm. In fact, a sufficient condition for the existence of equilibrium capital and output sequences for all firms is the existence of a joint probability measure over all technique choices which is consistent with the conditional measures (3). My 1990 paper verifies that such a joint measure exists for any initial conditions ω_0 .

Let us now restrict the conditional probabilities in order to discuss multiplicity and dynamics. Past choices of technique 1 are assumed to improve the current relative productivity of the technique. As a result, technique 1 choices will propagate over time. Further, it is assumed that $\omega_i = 1$ is a steady state, which means that when all productivity spillovers are active, the effects are so strong that high production is always optimal.

ASSUMPTION 3: Impact of past technique choices on current technique probabilities.²

Let ω and ω' denote two realizations of ω_{i-1} . If $\omega_j \geq \omega'_j \forall j \in \Delta_{k,l}$, then

A. $\text{Prob}(\omega_{i,t} = 1|\omega_{j,t-1} = \omega_j \forall j \in \Delta_{k,l})$

$$\geq \text{Prob}(\omega_{i,t} = 1|\omega_{j,t-1} = \omega'_j \forall j \in \Delta_{k,l}).$$

B. $\text{Prob}(\omega_{i,t} = 1|\omega_{j,t-1} = 1 \forall j \in \Delta_{k,l}) = 1.$

Whenever some industry chooses $\omega_{i,t} = 0$, a positive productivity feedback is lost. Different configurations of choices at $t-1$ determine different production sets and conditional technique choice probabilities for

²This assumption can be reformulated in terms of restrictions on the technique-specific production functions.

each industry. I bound the technique choice probabilities from below and above by $\Theta_{k,l}^{\min}$ and $\Theta_{k,l}^{\max}$, respectively.

$$(4) \quad \Theta_{k,l}^{\min} \leq \text{Prob}(\omega_{i,t} = 1 | \omega_{j,t-1} = 0$$

$$\text{for some } j \in \Delta_{k,l}) \leq \Theta_{k,l}^{\max}.$$

Since $\omega_i = 1$ is an equilibrium, multiple equilibria exist if for some initial conditions, $\omega_i = 1$ fails to emerge as t grows. Notice that even if $\omega_0 = 0$, favorable productivity shocks will periodically induce industries to produce using technique 1. The choice of technique 1 by one industry, through the complementarities, increases the probability that the technique is subsequently chosen in several industries. With strong spillovers, these effects may build up, allowing $\omega_i = 1$ to emerge from any initial conditions. The model therefore allows us to analyze the stability of a high aggregate output equilibrium from arbitrary initial conditions.

In fact, the limiting behavior of the economy is determined by the bounds $\Theta_{k,l}^{\min}$ and $\Theta_{k,l}^{\max}$. If the probability of high production by an industry is sufficiently large for all production histories, then the spillover effects induced by spontaneous technique 1 choices cause the economy to iterate towards high production. Alternatively, if technique 1 probabilities are too low in the absence of active spillovers, spontaneous technique 1 choices will not generate sufficient momentum to achieve the $\omega_i = 1$ equilibrium. $\Theta_{k,l}^{\min}$ and $\Theta_{k,l}^{\max}$ bound the degree of complementarity in the economy. Large values of $\Theta_{k,l}^{\min}$ imply complementarities are weak as technique 1 is chosen relatively frequently regardless of the past. Conversely, small values of $\Theta_{k,l}^{\max}$ imply strong complementarities; the probability of current high production is very sensitive to past technique choices. Theorem 1 (proven in my 1990 paper) shows how long-run industry behavior is jointly determined by initial conditions and conditional technique probabilities.

THEOREM 1: *Conditions for uniqueness vs. multiplicity of long-run equilibrium.*

For every nonnull index set $\Delta_{k,l}$, there exist numbers $0 < \underline{\Theta}_{\Delta_{k,l}} < \bar{\Theta}_{\Delta_{k,l}} < 1$ such that

A. If $\Theta_{k,l}^{\max} \leq \underline{\Theta}_{\Delta_{k,l}}$, then

$$\lim_{t \rightarrow \infty} \text{Prob}(\omega_{i,t} = 1 | \omega_0 = 0) < 1.$$

If complementarities are sufficiently strong, no industry converges to the high production technique almost surely from economywide low production technique initial conditions.

B. If $\Theta_{k,l}^{\min} \geq \bar{\Theta}_{\Delta_{k,l}}$, then

$$\lim_{t \rightarrow \infty} \text{Prob}(\omega_{i,t} = 1 | \omega_0 = 0) = 1.$$

If complementarities are sufficiently weak, each industry converges to the high production technique almost surely from economywide low production technique initial conditions.

One can associate $\omega_i = 1$ with the equilibrium that would emerge if all firms chose their production levels cooperatively. If production through technique 1 is sufficiently large for $\omega_i = 1$ versus any other configuration, then $\omega_i = 1$ emerges as the cooperative equilibrium after one period. Consequently, incompleteness of markets lowers the mean and increases the variance of industry and aggregate output along the inefficient equilibrium path, as technique choices fluctuate over time. When industries fail to coordinate, production decisions become dependent on idiosyncratic productivity shocks. Observe that the volatility associated with the inefficient equilibrium is caused by fundamentals. Simulations in both of my earlier papers show that aggregate output can obey a wide range of AR processes, depending on $\Delta_{k,l}$.

III. Path Dependence and Aggregate Shocks

Now consider the role of the aggregate shocks ξ_t . By affecting many industries simultaneously, these shocks act in a way analogous to changing the initial conditions of the economy. Path dependence occurs as

one realization of ξ_t permanently changes the equilibrium in the absence of future offsetting shocks. I assume that sufficiently unfavorable aggregate productivity draws make technique 1 unlikely whereas sufficiently favorable draws ensure the use of the technique.

ASSUMPTION 4: *Impact of aggregate shocks on technique choice.*

There exist numbers a and b , with $\text{Prob}(\xi_t \leq a)$ and $\text{Prob}(\xi_t \geq b)$ both nonzero, such that³

$$A. \quad \text{Prob}(\omega_{i,t} = 1 | \xi_t \leq a, \omega_{j,t-1} = 1 \forall j \in \Delta_{k,i}) \\ \leq \underline{\Theta}_{\Delta_{k,i}}.$$

$$B. \quad \text{Prob}(\omega_{i,t} = 1 | \xi_t \geq b, \omega_{j,t-1} = 0 \forall j \in \Delta_{k,i}) \\ = 1.$$

When this assumption holds, aggregate shocks can have an indefinite effect on real activity. My 1991 paper verifies

THEOREM 2: *Path dependence due to aggregate shocks.*

Let $\xi_t = 0 \forall t > T$ and $\Theta_{k,i}^{\max} \leq \underline{\Theta}_{\Delta_{k,i}}$. The economy exhibits path dependence as the realization of ξ_T affects the limiting technique choice probabilities for all industries.

$$A. \quad \lim_{t \rightarrow \infty} \text{Prob}(\omega_{i,t} = 1 | \xi_T \leq a) < 1.$$

$$B. \quad \lim_{t \rightarrow \infty} \text{Prob}(\omega_{i,t} = 1 | \xi_T \geq b) = 1.$$

This result shows how fluctuations can be persistent. For example, once many sectors simultaneously decline due to an adverse aggregate shock, productivity-enhancing complementarities are lost until a subsequent favorable draw restores them. If ξ_t is ergodic, then the economy will cycle between the equilibria.

Several interpretations beyond productivity can be applied to the aggregate shocks. Interpreting ξ_t as a proxy for the financial sector, the model indicates how the breakdown of financial institutions, such as occurred during the Great Depression, can cause indefinite output loss. Alternatively, my 1990 paper shows how ξ_t can represent the cost of production inputs provided by leading sectors such as transportation or steel. In this case, the growth of leading sectors improves the relative profitability of high production, which can lead to a takeoff in growth as the economy shifts across equilibria.

Identifying the Hand of Past: Distinguishing State Dependence from Heterogeneity

By JAMES J. HECKMAN*

A basic problem in social science is to ascertain the importance of initial endowments on subsequent outcomes of a dynamic process. Interest in this topic centers on two distinct issues: (a) Do initial endowments have a temporally persistent effect on outcomes (i.e., is there "heterogeneity")?; (b) Are the effects of initial endowments attenuated or accentuated by subsequent experiences of the process being studied or by related processes (i.e., is there "state dependence")?

These two questions show up in a variety of contexts. 1) The importance of family background on a person's subsequent education and earnings is a hotly debated topic. Do market or nonmarket mechanisms reinforce or diminish initial endowments? 2) The incidence of criminal activity is concentrated among a small population of repeated offenders. Are certain persons "prone" to criminality, or does crime breed crime? 3) Are persons who experience unemployment more likely to experience future unemployment due to loss of work experience or market stigma? 4) Does early entry into an industry confer an advantage of incumbency, or does it merely proxy the basic managerial and innovative ability of early entrants?

Many formal models of state-dependent processes or processes with persistent effects of initial conditions have been formulated. Invariance of steady states to initial endowments was viewed as a desirable feature of an economic model in the 1960's and 1970's. Path-dependent synergism and nonergodicity are fashionable features of models today. Is the choice between models

with long-run dependence on initial conditions and those without solely a matter of intellectual esthetics? Can data discriminate between these two classes of models? How many economically extraneous statistical "regularity conditions" have to be imposed in order to distinguish between these models? How many and what kind of *maintained* assumptions are required in order to let the data speak on these important questions?

In this paper I focus on one nonergodic model that receives much attention in the literature—the model of "duration dependence" and "heterogeneity" discussed by Herbert Silcock (1954) and also examined by Tony Lancaster (1979), Chris Elbers and Geert Ridder (1982), myself and Burton Singer (1984), and myself and Bo Honoré (1989).

I. The Problem of Separating Heterogeneity from Duration Dependence

The length of time in a state, L , and its determinants are the objects of interest. For example, the length of time that a new entrant firm survives in an industry, the length of an unemployment spell or a job spell or a strike, the length of time a person spends in school, or the time to a first birth are all objects of interest in current research. For simplicity, assume a continuous time model.

A set of explanatory variables is thought to explain L , but in addition there is some "randomness" or unpredictability given the explanatory variables. Outcomes depend on a larger set of variables than the economic analyst has at his or her disposal. We write (X, Θ) where X is a vector of observed explanatory variables and Θ is a scalar unobserved variable known to the agent but not the econometrician. The assumption that Θ is scalar is made for analytical con-

*University of Chicago, Chicago, IL 60637. This work was supported by NSF-87-10145 and NIH grant HD-19226. I have benefited from discussions with Ricardo Barros and Bo Honoré.

venience. The assumption of "randomness" is that the distribution of L is nondegenerate given (X, Θ) , that is,

$$(1) \quad \Pr(L \leq l|x, \theta) = F(l|x, \theta).$$

If (X, Θ) fully explain durations, the probability on the left would be zero or one. The distinction between Θ and the unobservable giving rise to the nondegenerate conditional distribution of L is arbitrary. Distribution (1) is of economic interest if agents make decisions based on Θ but not on the random components that make the distribution nondegenerate given (X, Θ) . Then (1) can properly be called a structural distribution and is an object of economic interest.

In duration analysis it is convenient to work with the survivor function: $S(l|x, \theta) = \Pr(L > l|x, \theta)$, the conditional probability that a spell exceeds length l . To avoid technicalities, assume that L is continuously distributed so the density of L is well defined. The structural conditional hazard rate or exit rate from the spell is denoted $h(l|x, \theta)$. If h is increasing in l , positive duration dependence is said to be present for those values of l . If h is decreasing, negative duration dependence is said to be present. In either case, state dependence (or one form of the hand of the past) is present because the length of time spent in a state determines the conditional exit rate from the state.

For time-invariant (X, Θ) or for time-varying (X, Θ) satisfying the conditions given in my article with James Walker (1990a),

$$(2) \quad S(l|x, \theta) = \exp - \int_0^l h(u|x(u), \theta(u)) du.$$

The survivor is the inverse of the exponentiated integrated hazard.¹ For analytical convenience I assume that $\Theta(u) = \Theta$ is constant for all u and is a scalar random variable. Its distribution function is $G(\theta)$. The variable Θ is assumed statistically independent of X , and can thus be interpreted

as a time-invariant endowment or propensity.

The problem of distinguishing state dependence from heterogeneity (or initial endowments) can now be stated precisely. The data determine the conditional distribution of L given X which is the *mean* conditional survivor function:

$$(3) \quad S(l|x) = \int_{\theta} S(l|x, \theta) dG(\theta) \\ = \int_{\theta} \exp \left(- \int_0^l h(u|x(u), \theta) du \right) dG(\theta)$$

where θ is the support of Θ . Associated with $S(l|x)$ is the empirical hazard

$$(4) \quad h(l|x).$$

A standard result in the literature establishes that (4) is biased toward negative duration dependence relative to $h(l|x, \theta)$.² The more mobility-prone agents exit spells more rapidly producing a distribution of Θ conditional on L and X that is weighted toward less mobile values.

The issue is whether or not it is possible to identify $G(\theta)$ and $h(u|x(u), \theta)$ from $S(l|x)$. Without further structure imposed, it is not. There is no way to separate out the contributions of state dependence from heterogeneity in a completely general model. The data do not "speak for themselves" except in the case where $h(l|x)$ shows positive duration dependence. For this to arise, $h(l|x, \theta)$ must show positive duration dependence at least for certain intervals of the support of Θ . (See myself and Singer, 1985.)

II. Separability as an Avenue of Identifiability

One way to answer the stated question is to impose specific functional forms. My article with Singer (1984) presents identification conditions for a variety of conventional models in which $h(\cdot|\cdot)$ is specified to be-

¹For general time-varying explanatory variables, relation (2) is not true although it is commonly assumed to be true in applied work.

²See Proposition 1 in my book with Singer (1985, p. 53).

long to a parametric family and $G(\theta)$ is assumed to be a proper probability distribution but its functional form is not specified. Identification through explicit functional form assumptions about both h and G is conventional but controversial. See the examples of the consequences of misspecification discussed in my book with Singer (1985).

An alternative and somewhat more general route to *nonparametric* identification is to characterize the hazard in some more abstract way. One starting point is to invoke a separability restriction of the sort often made in consumer and producer theory,

$$(5) \quad h(l|x) = m(l|x)\theta.$$

Writing $M(l|x) = \int_0^l h(u|x(u)) du$, we conclude that

$$(6) \quad S(l|x) = \int_{\theta} [\exp - M(l|x)\theta] dG(\theta).$$

In terms of a transformed time scale, $M(L|x)$ is an exponential random variable conditional on θ . The transformed dependent variable has the conditional expectation $E(\ln(M(L|x)|\theta)) = \Gamma'(1) - \ln \theta$, where Γ is the gamma function. Written as a familiar-looking regression equation, the problem of identifying the hand of the past is to determine M and the distribution of Θ from the regression

$$(7) \quad \ln M(L|x) = \Gamma'(1) - \ln \theta + V$$

where $E(V) = 0$, $\text{Var}(V) = \pi^2/6$.³ The severity of the identification problem is evident from (7).

Representation (6) reveals the nature of the available sample information. Level sets of $S(l|x)$, that is, $\{(l, x): S(l|x) = s\}$ trace out level sets of $M(l|x)$. If $M(l|x)$ is differentiable in x , we know the ratio of partial derivatives of M when the right-hand sides

of the following expressions are well defined:

$$(8) \quad \frac{\frac{\partial M(l|x)}{\partial x_i}}{\frac{\partial M(l|x)}{\partial x_j}} = \frac{\frac{\partial S(l|x)}{\partial x_i}}{\frac{\partial S(l|x)}{\partial x_j}},$$

$$\frac{\frac{\partial M(l|x)}{\partial x_i}}{\frac{\partial M(l|x)}{\partial l}} = \frac{\frac{\partial S(l|x)}{\partial x_i}}{\frac{\partial S(l|x)}{\partial l}}$$

where x_i, x_j are elements of x . Assuming $M(0, x) = 0$ for all x (so there are no jumps in the hazard at zero) and $E(\Theta) < \infty$, the right derivative of $S(l|x)$ evaluated in the neighborhood of $l = 0$ is

$$\left. \frac{\partial S(l|x)}{\partial l} \right|_{l=0} = - \left. \frac{\partial M(l|x)}{\partial l} \right|_{l=0} E(\Theta).$$

If $E(\Theta) = 1$ or some other known constant, the magnitude of the local hazard is known for all x .

This information does not suffice to identify M or G . A certain class of monotonic transformations of M explains the data equally well. Denote a member of this class by $J(0) = 0$.

$$(9) \quad S(l|x) = \int_{\theta} [\exp - [M(l|x)]\theta] dG(\theta) \\ = \int_{\theta^*} [\exp - [J(M(l|x))\theta^*] dG^*(\theta^*)$$

where Θ^* is a random variable in general distinct from Θ with distribution G^* .

Observe that $S(l|x)$ is both an exponential mixture of M and an exponential mixture of $J(M)$. As noted by William Feller (1971, p. 452), every mixture of exponentials is an infinitely divisible distribution so by Theorem 1 of Feller (p. 450): $S(M) = e^{-\psi(M)}$ and $S(J) = e^{-\psi^*(J(M))}$ where ψ and ψ^* satisfy the condition that $\psi(0) = \psi^*(0) = 0$ and both have a completely

³See the derivation in Chris Flinn and myself (1982, Appendix B).

monotone first derivative.⁴ Since both $S(M(l|x))$ and $S(J(M(l|x)))$ equal $S(l|x)$ for the same values of l and x , the equivalence class is defined as containing those J such that

$$(10) \quad \psi(M) = \psi^*(J(M)).$$

The requirement that ψ' and $(\psi^*)'$ are completely monotone restricts the admissible J . If $\psi' / (\psi^*)'$, $[(\psi^*)' \neq 0]$ is completely monotonic, then so is J' . Repeated differentiation of (10) produces an algorithmic definition of the derivatives of J . My article with Walker (1990b) uses these results for a class of exponential models ($M(l|x) = l$) and demonstrates the equivalence of a broad class of apparently different duration models within the class of mixture of exponentials models and shows the practical importance of this equivalence for a problem in demography.

Conventional duration models invoke additional separability assumptions:

$$(11) \quad M(l|x) = Z(l)K(x)$$

to produce the "proportional hazards" model. Z is assumed to be nonnegative, differentiable, and monotone increasing in l . $K(x)$ is nonnegative. The previous assumptions ensure that $Z(0) = 0$.

Identification in this class of models has received much attention for the case when X is time invariant. Elbers and Ridder establish that if $E(\Theta) < \infty$ and X assumes at least two distinct values, Z , K , and G are nonparametrically identified. Singer and I (1984) replace the finite mean of Θ assumption with a tail condition on G . Ricardo Barros and Honoré (1988) show that for this model $J(M) = aM^b$, $0 < a$, $0 < b \leq 1$ so J' is completely monotonic. They prove that the components of proportional hazards models are identified up to an arbitrary normalization and up to arbitrary powers (b).⁵

⁴Thus letting $R = \psi'$, R is completely monotone if $(-1)^n R^{(n)}(M) \geq 0$ for all nonnegative integer n and for all $M > 0$ where (n) denotes the n th derivative.

⁵See also the discussion in my book with Singer (1985, p. 64).

(See also Ridder, 1990.) By restricting the mean of Θ or the tail of G , one can avoid this arbitrariness. But such restrictions are themselves arbitrary. Tails of G are not known in advance. Finiteness of the mean for unobservable Θ is not necessarily a reasonable assumption. Models with infinite means for Θ produce entirely reasonable duration models.

Honoré (1990) establishes that if the elements of X are time varying, are not functionally dependent on l , and if one coordinate of X has discrete jumps for a proportion of the population strictly between zero and one and X is time invariant for the rest of the population, then Z , K , and G are nonparametrically identified without invoking arbitrary tail conditions for G or finite mean conditions.

It is interesting to contrast these results with those achieved from an *accelerated hazard* model:

$$(12) \quad M(l|x) = Z(lK(x)).$$

For this model, the assumption $E(\Theta) < \infty$ or the other assumptions do not identify Z or G . However, if $Z'(0) > 0$ and $E(\Theta) < \infty$, and adopting the *normalization* $K(x_*) = 1$, then $K(x)$ is nonparametrically identified up to an arbitrary positive scale.

$$\frac{\frac{\partial S(t|x)}{\partial t}}{\frac{\partial S(t|x_*)}{\partial t}} \bigg|_{t=0} = K(x)$$

We may rewrite (9) using known $q = lK(x)$, to reach $S(q) = \int_0^\infty [\exp - Z(q)\theta] dG(\theta)$. The terms Z , G are not identified except for the special case when $Z(t) = at^b$ (the Weibull) when the proportional hazard model and accelerated hazard model coincide. In that case it is not necessary to have any regressor in order to identify a , b , and G (see myself and Singer, 1984). My article with Honoré notes that $K(x)$ can be identified under weaker assumptions than are required to identify Z and G in both the proportional hazard and accelerated hazard models. It also notes that the accelerated

failure time model is not nonparametrically identified.⁶

Barros (1986) considers the case $M(I|x) = N(Z(I), K(x))$ where Z and K have the properties assumed in the discussion of the proportional hazard model without time-varying variables and where N is assumed known and $N(Z, \cdot) = 0$ if and only if $Z = 0$, N is differentiable with respect to K , $N_K \neq 0$ for $Z \neq 0$ and $N_Z(0, \cdot)$ is finite and different from zero with a well-defined inverse. For $E(\Theta) < \infty$, he proves that Z , K , and G are nonparametrically identified.

III. Conclusion

The ability to distinguish between heterogeneity and duration dependence in single-spell duration models rests critically on maintaining explicit assumptions about the way unobservables and observables interact. A general nonseparable model is nonparametrically underidentified. Separable models are identified subject to additional assumptions on the nature of the explanatory variables (as in Honoré) or subject to restrictions on unobservables. Economically extraneous statistical assumptions drive the answer to the stated question. Viewed as a prototype for identification in general non-ergodic models, these results are not encouraging.⁷

⁶The same qualitative results hold for the more natural version of the accelerated hazard model $Z(tK(x)\theta)$.

⁷Honoré demonstrates how access to multiple spell data facilitates identification of single spell hazards. My article with Honoré discusses conditions for non-parametric identifiability of the competing risks model.

History and Industry Location: The Case of the Manufacturing Belt

By PAUL KRUGMAN*

If there is one single area of economics in which path dependence is unmistakable, it is in *economic geography*—the location of production in space. The long shadow cast by history over location is apparent at all scales, from the smallest to the largest—from the cluster of costume jewelry firms in Providence to the concentration of 60 million people in the Northeast Corridor.

This paper illustrates path dependence in economic geography by describing a particular historical example, the persistence of the U.S. “manufacturing belt,” and a simple model that helps make sense of that example.

I. The U.S. Manufacturing Belt

Early in this century, geographers noted that the great bulk of U.S. manufacturing was concentrated in a relatively small part of the Northeast and the eastern part of the Midwest. This manufacturing belt took shape in the second half of the nineteenth century, and proved remarkably persistent. Harvey Perloff (1960) estimated that as late as 1957 the manufacturing belt still contained 64 percent of U.S. manufacturing employment—only slightly reduced from its 74 percent share at the turn of the century.

Even this number understates the dominance of the belt, because during its heyday most manufacturing outside it consisted either of processing of primary products or of production for a very local market. That is, the manufacturing belt contained virtually all manufacturing that did not need either to be close to the consumer or close to specific natural resources.

The manufacturing belt persisted even as the center of gravity of agricultural and

mineral production shifted far to the West. In 1870, the Northeast and East North Central regions (within which the emerging manufacturing belt lay) accounted for 44 percent of U.S. “resource extraction” employment (agriculture, mining, forestry, fisheries). By 1910, this share had already fallen to 27 percent; yet these regions still accounted for 70 percent of manufacturing employment. And whereas the belt’s share of manufacturing employment understates its manufacturing dominance, its share of resource employment overstates its resource base, since much of the agriculture in or near the manufacturing belt took place less because of the suitability of the land than because of proximity to urban centers.

The manufacturing belt’s persistent dominance evidently reflects some kind of external economies. But what was the nature of these external economies? I will sketch out a simple model that surely does not capture the full story, but is strongly suggestive of the kind of explanation that is needed.

II. A Core-Periphery Model¹

A core-periphery pattern like that of industrial America can emerge from the interaction of increasing returns, transportation costs, and demand. Given sufficiently strong economies of scale, each manufacturer wants to serve the national market from a single location. To minimize transportation costs, she chooses a location with large local

¹This paper presents only a sketch of a model. It will be apparent that this sketch is sloppy about a number of issues, including: what is the market structure in manufacturing; what happens to profits, if any; and what resources are used in both fixed costs and transportation. It is possible to derive similar results in a fully specified general equilibrium monopolistic competition model (see my 1991 article). I adopt the more *ad hoc* approach here for ease of exposition.

*Department of Economics, MIT, Cambridge, MA 02139.

demand. But local demand will be largely precisely where the majority of manufacturers choose to locate. Thus there is a circularity that tends to keep a manufacturing core in existence once it is established. (This is not an original story: it is more or less explicit in the work of such geographers as Allan Pred, 1966, and David Myers, 1983.)

Imagine a country in which there are only two possible locations of production, East and West, and two kinds of production. Agricultural goods are produced using a location-specific factor (land), and as a result the agricultural population is exogenously divided between the locations; we assume that the division is 50–50.

Manufactured goods (of which there are many symmetric varieties) can be produced in either or both locations. If a given manufactured good is produced in only one location, transportation costs must be incurred to service the other market. On the other hand, if the good is to be produced in both locations, an additional fixed set-up cost is incurred. The manufacturing labor force in each location is proportional to manufacturing production in that location.

Finally, assume that the *demand* for each manufactured good in each location is strictly proportional to that location's population.

The basic workings of the model can then be illustrated by Figure 1. On the horizontal axis we measure the share of the manufacturing labor force employed in West, on the vertical axis the share of West in the total population. The line *MM* represents the dependence of the distribution of manufacturing on the distribution of population; the line *PP* the converse effect of manufacturing on population distribution.

If West has a small share of the population, it will not be worth incurring the fixed costs of establishing a manufacturing facility there; it is cheaper to serve the market from facilities in East. Conversely, if West has a large share of the population, it is not worth producing manufacturers in East. A sufficiently equal division of population might, however, lead manufacturers to produce locally for both markets. Putting these observations together, we get the illustrated shape

FIGURE 1

of *MM*: no western production for low western population, production proportional to population for intermediate levels, no eastern production if the West is big enough.

The more manufacturing that takes place in West, the larger the western share of the total population; but not in proportion, because some people are immobile farmers. Thus *PP* is upward sloping, but flatter than the 45° line.

Suppose that manufacturing production adjusts gradually toward its equilibrium level. Then the dynamics are illustrated by the arrows in Figure 1. There are three stable equilibria: manufacturing may be concentrated in either location, at 1 or 3, or it may be equally divided, at 2.

The picture need not look like this: a core-periphery geography may be unsustainable because the “centripetal” pull of a manufacturing core is weaker than the “centrifugal” pull of the dispersed agricultural sector. We can easily derive a necessary condition for concentration of manufacturing production in one location. Consider a typical manufacturing firm with total sales of x ; let π be the proportion of the population that is employed in manufactures; let F be the fixed cost that the firm must incur to produce in both locations; and let t be the transportation cost per unit shipped between locations. Now we ask: is a situation with all manufacturing concentrated in East an equilibrium?

With all manufacturing in East, West has a share of total population equal to only $(1 - \pi)/2$. The transportation cost of serving this market from East for a typical manufacturer is therefore $tx(1 - \pi)/2$. The cost of setting up a plant in West is F . So a concentration of production in East, once established, will persist as long as $F > tx(1 - \pi)/2$. If this criterion is not met, there is no path dependence: the long-run geography of manufactures will follow that of agriculture.²

We can immediately see that whether geography is path dependent is determined by three parameters: large F , that is, sufficiently strong economies of scale; small t , that is, sufficiently low costs of transportation; and large π , that is, a sufficiently large share of "footloose" production not tied down by natural resources.

We can now tell a stylized story of the emergence of the manufacturing belt. In the early United States, with its primarily agricultural population, where manufacturing was marked by few scale economies, and where transportation was costly, no strong geographical concentration could occur. As the country began its industrial transition, manufacturing arose in areas that contained most of the agricultural population outside the South. During the second half of the nineteenth century, however, manufacturing economies of scale increased, transportation costs fell, and the share of the population in nonagricultural occupations rose. The result was that the initial advantage of the manufacturing belt was locked in. Even though new land and new resources were exploited to the West and even though slavery ended, for three-quarters of a century the pull of the established manufactured areas was strong enough to keep the manufacturing core virtually intact.

Of course this story oversimplifies. In particular, it says nothing about the sources of local specialization within the manufactur-

ing belt—about why Detroit emerged as the automotive center, New York as the garment center, Grand Rapids as the furniture center, etc. Yet it surely captures an important aspect of what happened. And it also contains elements (increasing returns at the level of individual firms, and external economies resulting from the interaction of these firms' decisions) that will reappear as one further elaborates the story.

III. Further Thoughts

The case of the U.S. manufacturing belt is of substantial interest in its own right. The rise and persistence of that belt is an important yet much neglected aspect of U.S. economic history. More important than its immediate significance, however, is what the history of manufacturing location says about the nature of our economy in general. And what it says is Nicholas Kaldor (1972), Paul David (1985), and Brian Arthur (1989) were right—that increasing returns and cumulative processes are pervasive and give an often decisive role to historical accident.

It is also interesting that the story of the manufacturing belt reaches back to the mid-nineteenth century. It is common to argue that external economies and cumulative processes have become more important in recent decades because of the growing importance of high technology. The geographical concentration of manufacturing in the United States took shape, however, in the age of steam, not that of microprocessors. So it is not simply true that our economy is not now well described by the conventional constant returns model. It never was.

Complementarities, Momentum, and the Evolution of Modern Manufacturing

By PAUL MILGROM, YINGYI QIAN, AND JOHN ROBERTS*

In the nineteenth century, the railroad and telegraph were at the center of a set of technological advances, physical investments, and managerial innovations that transformed American industry (Alfred Chandler, 1977). Later, the automobile and telephone played a similar role in another transformation.

Today, the high-tech industries include computers, telecommunications, and electronics. Working on our remarkably powerful computers (even as they rapidly become obsolete), co-authoring papers by electronic mail and fax, and conversing on our portable cellular telephones, we are struck by what appears to be a self-supporting and -reinforcing dynamic to the technological improvements across the electronics industries. An advance almost anywhere in the sector seems to call forth more advances across the sector.

These advances are occurring contemporaneously with a broad pattern of other changes, not only in the electronics industries, but in manufacturing more generally, and not just in hardware, but in methods and organization as well. A new paradigm has begun to emerge. In contrast to traditional manufacturing firms, modern firms frequently 1) make greater use of flexible, programmable equipment and of computer-aided design and manufacturing technologies, 2) have fewer job classifications, 3) offer more varieties of their major products and/or update their product lines more frequently, 4) put more emphasis on speed in

order processing, production, and delivery, 5) hold much lower inventories of intermediate and finished goods, 6) rely on subcontractors to supply a greater proportion of the total value added, and 7) overlap design, product, and process engineering to speed the introduction of new products. These features of modern manufacturing firms encompass technology choices, marketing strategies, personnel policies, supplier relations, lines of internal communications, and other operational policies in a far-reaching and coherent pattern whose existence, in the words of Michael Piore (1986), poses a "challenge to economic theory."

In a recent paper, Milgrom and Roberts (1990), proposed a theory to explain the emergence of this new paradigm, arguing that the various characteristics and activities described are mutually complementary and so tend to be adopted together, with each making the others more attractive. In that theory, the falling costs of high-speed data communication, data processing, and flexible, multitask equipment lead to increases in the directly affected activities, which through a web of complementarities then lead to increases in a set of related activities as well.

Although the costs of flexible machinery and data communication and processing surely have fallen substantially in recent decades, an analysis that takes these changes as exogenous does not constitute a full explanation of the pattern of change that we observe. One must ask: Why are these particular costs falling relative to others? Here we enrich the Milgrom-Roberts analysis by adding a dynamic to it: innovations in the manufacture of basic inputs both arise in response to a growing market for those inputs and simultaneously encourage that growth. This reflects a fundamental complementarity between the level of any activity and investments that reduce its marginal

*Department of Economics (Milgrom and Qian) and Graduate School of Business (Roberts), Stanford University, Stanford, CA 94305. We thank Avner Greif for his helpful comments on an earlier draft. Financial support from the National Science Foundation (Milgrom and Roberts) and the Robert and Anne Bass Faculty Fellowship (Roberts) is gratefully acknowledged.

cost. In our model, innovation results in falling marginal costs that lead to increasing usage of the inputs, which in turn leads to increasing investments in the development of complementary techniques, that further raise the underlying demand for the inputs, leading to more innovations, and so on, just as we have noted within the electronics industry itself.

Significantly, just as this verbal sketch requires no assumptions about the presence or absence of returns to scale, neither does our formal analysis: The momentum of the system of changes we analyze results entirely from the positive feedback effects that each of a group of core activities and practices has on the *other* activities and practices in the group.¹

Our model also adds to the Milgrom-Roberts model groups of "additional" activities, each of which may interact with any one core activity in a general way but that are not themselves part of the *mutually complementary core group*.

Our formal analysis is summarized in two theorems. Most important is the *Momentum Theorem*: this asserts that once the system begins along a path of growth of the core variables, it will continue forever along that path or, more realistically, until unmodeled forces disturb the system. Second, the *Reduced-Forms Theorem* concerns the set of models that have a reduced form to which the Momentum Theorem applies.

I. The Downstream Industry Model and the Reduced-Forms Theorem

We suppose that there is a representative firm in the "downstream manufacturing industry" whose profit function in period t depends on the current state of (public) knowledge, represented by a vector $\theta(t) \in \mathbb{R}^k$, on a vector of core decision variables

$x = (x^1, x^0) \in \mathbb{R}^{m+n}$, where the variables $x^1 = (x_1, \dots, x_m)$ denote purchased *inputs* and the variables $x^0 = (x_{m+1}, \dots, x_{m+n})$ denote the *other* core decision variables, and finally on various variables outside the core group and denoted by $\{y^i(t); 1 \leq i \leq m+n\}$. The firm's payoff takes the form:

$$\rho(x(t), \theta(t)) + \sum_j \phi_j(x_j(t), y^j(t)) - R(x^1(t)),$$

where $R(x^1(t))$ is the amount paid for inputs. If ρ is smooth, the assumptions that the components of x are mutually complementary and that their effectiveness is enhanced by technical knowledge are represented by the inequalities $\partial^2 \rho / \partial x_i \partial x_j \geq 0$ for all $i \neq j$ and $\partial^2 \rho / \partial x_i \partial \theta_j \geq 0$ for all i and j , where $1 \leq i, j \leq m+n$. That is, the marginal product of any component of x is nondecreasing in the levels of the other arguments and in the level of technological knowledge. More generally, the first assumption is that ρ is *supermodular*, that is, for all x, x' , and θ ,

$$\rho(x, \theta) + \rho(x', \theta) \leq \rho(\text{Max}(x, x'), \theta) + \rho(\text{Min}(x, x'), \theta),$$

where Max and Min are taken component-by-component. The second is that ρ has *increasing differences*, that is, if for all $x \geq x'$, the difference $\rho(x, \theta) - \rho(x', \theta)$ is nondecreasing in θ . We emphasize that there are no assumptions made about the own second partial derivatives, $\partial^2 \rho / \partial x_i^2$, so that the profit function may be convex in x_i over some ranges and concave over others. No assumptions are made about returns to scale.

The y^i 's represent other variables, each of which interacts with at most one core variable. For example, if one of the core decision variables x_i is the level of inventories to hold, the y^i vector might include decisions about where to hold the inventory or how large the storage room should be. The restriction is that none of these should affect the returns to other core variables, such

¹ Indeed, our entire analysis is a purely ordinal one, that is, no step in the argument is affected if the variables are subject to arbitrary monotone rescalings. Since returns to scale is a cardinal concept, all of our conclusions apply without any assumptions about returns to scale.

as the flexibility of equipment or the number of job classifications.

We assume that each decision variable x_i or y^i is constrained to lie in some compact set $S(x_i)$ or $S(y^i)$, which may be finite or infinite. Our main conclusion about these noncore variables is that their presence has no qualitative effect on the analysis.

THEOREM 1. Reduced Forms: Suppose ρ and each ϕ_j ($j = 1, \dots, m + n$) is continuous. Then the reduced-form (gross) profit function of the manufacturing sector given by

$$(1) \quad \pi(x, \theta) = \text{Max}_y \rho(x, \theta) + \sum_j \phi_j(x_j, y^j),$$

is continuous, supermodular in x , and has increasing differences in (x, θ) .

PROOF:

Let $G(x) \equiv \text{Max}_y \sum_j \phi_j(x_j, y^j)$. Then, because of the separability of the y variables, $G(z) + G(z') = G(\text{Max}(z, z')) + G(\text{Min}(z, z'))$. So, for all θ , $[\pi(z, \theta) + \pi(z', \theta)] - [\pi(\text{Max}(z, z'), \theta) + \pi(\text{Min}(z, z'), \theta)] = [\rho(z, \theta) + \rho(z', \theta)] + [G(z) + G(z')] - [\rho(\text{Max}(z, z'), \theta) + \rho(\text{Min}(z, z'), \theta)] - [G(\text{Max}(z, z')) + G(\text{Min}(z, z'))] = [\rho(z, \theta) + \rho(z', \theta)] - [\rho(\text{Max}(z, z'), \theta) + \rho(\text{Min}(z, z'), \theta)] \leq 0$. The last inequality holds because $\rho(x, \theta)$ is supermodular in x for any given θ . Finally, from $\pi(z, \theta) - \pi(z', \theta) = \rho(z, \theta) - \rho(z', \theta) + G(z) - G(z')$, we conclude that $\pi(x, \theta)$ should also have increasing differences in (x, θ) since $\rho(x, \theta)$ has increasing differences in (x, θ) .

II. The Upstream Industry and the Contracting Equilibrium

We also suppose that there is a representative firm in the "upstream," input-producing sector. Its profit function is $R(x^I(t)) - C(x^I(t), T(t), \eta(t))$, where $\eta(t)$ is the "knowledge" vector describing knowhow in the input industry in period t and $T(t)$ is the level of technology it uses in producing its output. We assume that $-C$ is supermodular in (x, T) and has increasing differences in (x, T) and η . Thus, the core aspects of the technology are separable or

complementary ($\partial^2 C / \partial T_k \partial T_j \leq 0$) and there are no diseconomies of scope in producing the various inputs ($\partial^2 C / \partial x_i^I \partial x_j^I \leq 0$). Also, increases in both public knowledge $\eta(t)$ and the firm's own technology ($T(t)$) reduce its marginal cost of production: $\partial^2 C / \partial x_j^I \partial T_k \leq 0$ and $\partial^2 C / \partial x_j^I \partial \eta_k \leq 0$ for all j and k . Finally, accumulated public knowledge is assumed to reduce the marginal cost of technological improvements: $\partial^2 C / \partial T_j \partial \eta_k \leq 0$.²

Given the limited space, we set aside the model of consumers and questions of the nature and existence of equilibrium. Rather, we assume that the upstream firms and their suppliers arrange terms that are efficient for themselves, ignoring whatever effects their activities may have on the economywide accumulation of knowledge. This latter assumption (that firms ignore the effect of their efforts on public knowledge) is indicative of a free-rider problem and is most reasonable when the typical firm is not too large. Then, the industry equilibrium involves choosing x and T to maximize the objective:

$$(2) \quad \pi(x(t), \theta(t)) - C(x^I(t), T(t), \eta(t)),$$

where π is the reduced-form profit function given in (1).

III. Knowledge Accumulation Dynamics and the Momentum Theorem

The knowledge $\theta(t)$ and $\eta(t)$ at date t is assumed to be freely available to all firms. Suppose that $\theta(t+1) = f(\theta(t), \eta(t), x(t), T(t))$, and $\eta(t+1) = g(\theta(t), \eta(t), x(t), T(t))$, where both f and g are nondecreasing functions. That is, higher levels of the core activities in the downstream sector and higher levels of technology in the upstream sector combine with a higher initial

²Generally, using high-technology equipment may require both "knowledge" $\eta(t)$ and cash investment $I(t)$, for example: $T(t) = \eta(t)h(I(t))$, where $h' > 0$ and $h'' < 0$. In this example, the cost of achieving technology level T using knowledge η is $I = h^{-1}(T/\eta)$, which implies the required inequality: $\partial^2 I / \partial T \partial \eta < 0$.

state of knowledge today to produce a higher state of knowledge tomorrow. The model incorporates the possibility that learning by doing and high levels of activity in one industry increase learning in the other.

THEOREM 2. Momentum: *Suppose that for every given value of (θ, η) , there is a unique (x, T) that maximizes (2). If there is any time t such that $\theta(t) \geq \theta(t-1)$ and $\eta(t) \geq \eta(t-1)$, then for all times $s \geq t$, $x(s) \geq x(s-1)$, $T(s) \geq T(s-1)$, $\theta(s) \geq \theta(s-1)$ and $\eta(s) \geq \eta(s-1)$.*

PROOF:

By Theorem 1, $\pi(x, \theta) - C(x^I, T, \eta)$ is supermodular in (x, T) and has increasing differences in $(x, T; \theta, \eta)$. Therefore, given our hypothesis that $\theta(t) \geq \theta(t-1)$ and $\eta(t) \geq \eta(t-1)$, we conclude that $x(t) \geq x(t-1)$ and $T(t) \geq T(t-1)$ according to the Topkis's monotonicity theorem (Donald Topkis, 1978).³ $\theta(t+1) \geq \theta(t)$ and $\eta(t+1) \geq \eta(t)$ then follow immediately from the fact that f and g are nondecreasing. The theorem then follows by induction.

Although we have not explored it here, our model does allow the possibility of multiple steady states. Nevertheless, because our formal model has no durable capital in the firms and because our representative firms always contract efficiently, the possibility that expectations affect the path of the economy is excluded. Instead, following Paul David (1988) and Steven Durlauf (1990), we emphasize the role of history, featuring the momentum of the economic system.

IV. Conclusion

The Momentum Theorem shows that complementarities among a group of core activities and processes can account for the emergence of a persistent pattern of change,

even without any of the usual assumptions in the growth literature about economies of scale (see Paul Romer, 1986). Our method, emphasizing complementarities over issues of scale, also promises to clarify the logic of growth models and to allow a far richer modeling of the multifaceted processes of growth and development.

In Chandler's account of nineteenth-century American economic growth, for example, the emergence of the large industrial enterprise was accompanied not only by improvements in communications (telegraph) and transportation (railroads) that helped to create national markets, but also by innovations in finance (bond markets), management methods (cost accounting), large-scale manufacturing technologies (continuous process technologies), and so on. Each of these improvements and innovations were complementary to further growth of large enterprises, and the expanding scale of these enterprises correspondingly encouraged continuing technological, organizational and managerial advances.

Closely related to our ideas are some longstanding analyses of economic development, where the need to manage complementarities among investment projects has been noted by some economists (see Albert Hirschman, 1960). The questions addressed in these analyses are not merely ones of whether to develop or how to develop, but also *in which direction* to develop. An analysis of complementarities, richly conceived, seems indispensable to giving a satisfactory answer to these questions.

PRICE STICKINESS IN THEORY AND PRACTICE

Why are Prices Sticky? Preliminary Results from an Interview Study

By ALAN S. BLINDER *

Those of us who teach Keynesian economics (an increasing number these days) attach great importance to the phenomenon of wage and/or price "stickiness." It explains, for example, why recessions cure themselves only slowly and why changes in the money supply have real effects. In fact, Keynesian economics is sometimes characterized as the economics of nominal rigidities. Yet, more than a half-century after Keynes published *The General Theory*, the phenomenon itself remains poorly understood. Just why are wages or prices sticky?

It is not that economists have ignored these questions. One could literally fill many volumes with good empirical studies of wage and price stickiness, and many more with clever theories purporting to explain these phenomena. Yet, despite all this work, the range of admissible theories is wider than ever, and new theories continue to crop up faster than old ones are rejected. This lack of scientific progress makes one wonder

about the basic research strategy that economists have been pursuing. Is there a better way?

In Section I, I argue that traditional research strategies may be unpromising vehicles for learning about why prices are sticky; the time may have come to entertain new and unorthodox approaches. Section II defends the notation that interviews, in particular, can be a useful research tool in this area. Sections III and IV then describe the design of and summarize some preliminary findings from a large-scale interview study currently underway at Princeton. This paper is very much a progress report since the interviewing still has 9–12 months to go.

I. Why Interviews?

The standard program of scientific research in economics is to (a) develop a theory of some phenomenon, (b) formulate it in econometric terms, and then (c) test it with actual data. The theory is then either rejected or provisionally accepted, that is, allowed to survive to the next test. Unfortunately, this program has been singularly unsuccessful in the area of wage-price stickiness. Most economists would, I think, agree that we know next to nothing about which of several dozen theories of wage-price stickiness are valid and which are not. We might have expected statistical tests to have weeded out the weaker theories by now, especially since many of them have been around a long time. But, in fact, the survivorship rate rivals that of congressional elections. Why?

Part of the reason, no doubt, is that economists are fonder of building theories than of testing them. But I think the main reason is that most of the theories are *empty*

*Department of Economics, Princeton University, Princeton, NJ 08544. I owe many debts of gratitude: to the Russell Sage and Alfred P. Sloan Foundations for financial support; to Eric Wanner for persuading me to go ahead with the project; to Elie Canetti for extensive and excellent research assistance; to Phyllis Durepos for efficiently handling the considerable volume of office traffic; to my graduate student interviewers, Anthony Marcus, David Genesove, Katy Graddy, Dean Jolliffe, Harold Kim, John Leahy, Alec Levenson, John Penrod, Michael Quinn, Steve Schwartz, Tim Vogelsang, and David Zimmerman; to Bob Abelson, George Akerlof, Larry Ball, Olivier Blanchard, Elizabeth Bogan, Dennis Carlton, Russell Cooper, Bob Gordon, Bruce Greenwald, Glenn Hubbard, Tom Juster, Danny Kahneman, Anil Kayshap, Alan Krueger, David Romer, Julio Rotemberg, Bob Shiller, and Andy Weiss for helpful suggestions; and, especially, to the many business executives who took time out from their busy schedules to answer our questions.

in the following specific sense: Either they involve unobservable variables in an essential way, or they carry no real implications other than that prices are "sluggish" in some unmeasurable sense, or both. This makes econometric modeling a blunt, perhaps even useless, investigative tool. Let me illustrate.

To begin with, think about what we mean when we say that a theory predicts that prices are "sticky": Often nothing more than that prices adjust less rapidly than Walrasian market-clearing prices. But since equilibrium price movements often go unmeasured, it is hard to know whether actual prices are moving faster or slower than this norm. More important, all the theories share *exactly the same* prediction: that prices are sticky in this sense. So how are we to discriminate among them? It seems difficult even to imagine what a decisive test would look like, much less to carry one out.

A natural idea is to use each theory to derive other, auxiliary predictions, and then test these. Unfortunately, often there are no such predictions—or at least none that can be checked against actual data. One reason is that many of the theories are based on variables that are *unobservable* either in principle or in practice.

As an example of the former, consider the theory that firms hesitate to cut prices because they fear that customers will interpret a price cut as signal that quality has been reduced—*when, in fact, there has been no quality reduction*. Clearly, the theory is predicated on the existence of *unobservable* quality differences for, if consumers could observe quality readily, price would not play a signalling role. As an example of the latter, consider the so-called menu cost theory. In principle, fixed costs of changing prices can be observed and measured. In practice, such costs take disparate forms in different firms, and we have no data on their magnitude. So the theory can be tested at best indirectly, at worst not at all.¹

¹For example, the menu cost theory predicts firms will never make "small" price changes, which appears to be a testable proposition. But does it rule out price increases of 1 percent or 10 percent? Without measuring the menu costs, we cannot answer this question.

One might argue that theories that make identical predictions are, in an operational sense, the same theory; so it does not matter which theory is correct. In fact, however, it does matter. It matters for the value of economics as a descriptive science; and it matters for the conduct of macroeconomic policy because not all sources of price rigidity open the door to welfare-improving policies.

If it really matters which theory is correct, but conventional modes of economic inquiry cannot adjudicate the dispute, economic science would appear to be in deep trouble. Fortunately, one other common characteristic of the theories suggests a way out: Virtually every theory of price rigidity *describes a chain of reasoning which allegedly leads the firm to conclude that a change in price is inadvisable*.

That is what gave me the idea for an interview study. If actual decision makers really think the way one of these theories says, they ought to know that they do. If you ask them open-ended questions like, "Why don't you cut your prices when sales decline?," you may get shrugs or incoherent answers. But, if you confront them with the chain of reasoning they actually follow, they ought to recognize and agree with it. Conversely, if they explicitly deny the relevance or validity of a particular argument, then it is probably not governing their behavior. At least that is my methodological precept.

II. But Aren't Interviews Unreliable?

Economists are skeptical that you can learn much by asking people. We are trained to study behavior by watching what people *do* (usually in markets), not by listening to what they *say*. For example, critics will point out that subjects of interviews have no incentive to respond truthfully or thoughtfully; so *homo economicus* might refuse to cooperate or even give misleading answers. If the respondent has reason to conceal the truth or mislead the interviewer, this objection is probably a show stopper. But, in the case of price stickiness, people have no particular reason to conceal the truth. As long as people are not pathological liars, interviews may elicit useful information.

The thoughtfulness problem goes deeper. We all know the billiard ball analogy: A good pool player makes excellent use of the laws of physics without understanding them, and certainly without being able to articulate them. For this reason, many economists doubt that much can be learned by asking "economic players" about how they play the game. But I believe that more pointed questions, posed in plain English, can elicit useful answers. For example, if you ask a skilled billiards player whether he bases his shots on the principle that the angle of incidence equals the angle of reflection, he will probably look at you quizzically. But, if you take him to the table and, pointing to the proper angles, ask: "Do you try to make this angle the same as that angle?," I imagine he would respond in the affirmative.

Legitimate questions can also be raised about the size and representativeness of interview samples. Detailed case studies of two or three companies can, at most, provide anecdotes, not useful statistical information. And samples that are unrepresentative of the underlying population give no basis for drawing inferences about population statistics. But these are familiar problems, well known to any user of data. They are not reasons to reject interview evidence out of hand.

We should remember that theory and econometrics have their limitations, too. Theoretical deductions are often untested or, worse yet, *untestable*. Econometric evidence is often equivocal and/or subject to methodological dispute. The imperfect knowledge we can pick up from interviews and questionnaires should therefore not be compared to some epistemological ideal, but to the imperfect knowledge that nonexperimental scientists can deduce theoretically or glean from econometric studies. By this more reasonable standard of evidence, data culled from interviews certainly look admissible.

III. The Research Design

Along with a team of Princeton graduate students, I have now been in the business of interviewing executives about their pricing strategies since August 1988. Let me briefly

describe the research strategy and some of the tactics.

Designing the Questionnaire: The first step, obviously, was to decide which theories were to be tested and then to turn them into questions that ordinary people can understand. This selection process was not entirely objective; nor could it have been. In scouring the intellectual waterfront, I excluded theories that sounded silly or that actually *were* silly, or that seemed too complicated to be explained tersely in plain English. These omissions were not particularly costly; they did not disqualify any of the major competing theories.

Translating the equations and diagrams into English proved to be easy. My first stab at a questionnaire was tried out on many "guinea pigs" (including economists, business people, and a few scholars involved in survey research) and altered in literally hundreds of ways. But, in general, the current version of the questionnaire bears a striking resemblance to my original draft. Translating from technical journalese into English simply proved not to be very difficult. I took this to be a good omen.

However, one important caveat should be entered. Not infrequently, a question must be rephrased on the spot to make the respondent understand it. To do so successfully, an interviewer must be reasonably articulate, must be able to think on his or her feet, and, most importantly, must understand the economics well enough to paraphrase a question without changing its meaning. Thus professional pollsters will not do. Instead, my interviewers are carefully selected Princeton graduate students.

Eliciting Cooperation from Businesses: The next problem was getting our feet in the door and getting our questions answered by the right people. A low-response rate would obviously raise fears of selectivity bias.

A small-scale pilot study was used both to estimate the likely response rate in a large-scale study and to polish our questionnaire and interviewing techniques. We randomly selected 16 firms in the northeastern United States and wrote each an introductory letter requesting an interview. We then followed up with phone calls and/or further mail-

ings as necessary and, after considerable effort, successfully interviewed 8 companies. (These 8 companies are *not* included in the data reported below.) The estimated 50 percent response rate struck me as high enough to merit proceeding to the full study. So far, the response rate in the full study is running above 60 percent.

In addition, we had no trouble making connections with the person or persons in each company who could answer our questions. The number of "I don't know" responses has been small, and almost never do we hear, "You're asking the wrong person." Once in the door, we have found people more than willing to talk frankly. They find the questions interesting, mostly understandable, and not invasive of privacy.² Our experience, in fact, is that people are often eager to tell us things about which we would never have dared ask for fear that we would appear to be prying. We do, of course, promise confidentiality.

Getting Economists to Pay Attention: The hardest problem may yet lie ahead: Getting economists to pay attention to the results. Several concrete steps have been taken to increase the believability of the ultimate findings, whatever they may be. First, I wrote letters to the originators or major proponents of each theory. The letters explained the nature of the study, included a copy of the relevant portion of the questionnaire, asked for suggested improvements in the questions, and asked the "theorists" to suggest other testable implications of their theories. Most responded, sometimes offering useful ideas for modifying the questionnaire, which were adopted. Interestingly, however, not one person suggested a single further implication that could be tested in the questionnaire. This underscores the point I made earlier about the theories being empty.

Second, and much more important, we have taken great pains to ensure that the sample of firms is (a) large enough for seri-

ous statistical analysis, (b) randomly selected, and (c) representative of the private, for-profit GNP. To my knowledge, this is the first time anything like this has ever been attempted in an interview study. Since it is what makes the study unique, it is worth describing in some detail.

We purchased a tape listing firms with annual sales over \$10 million in the northeastern United States, an area which accounts for 40–45 percent of U.S. GNP. From this sampling universe, we eliminated government enterprises and nonprofits on the grounds that the theories we wanted to test were all about profit-seeking firms; this left almost 25,000 firms. We then assigned a sampling weight to each firm proportional to its value-added and drew a random sample of 400 firms, seeking to complete 200 interviews. (Remember, the estimated response rate was 50 percent.)

Notice that we excluded any company with annual sales under \$10 million, even though they employ nearly half the labor force. Why? Because there are so many of them, and the expense of reaching any sizable portion would be prohibitive. Clearly, an optimal experimental design would balance the value of the information obtained against the costs of obtaining it and would, therefore, undersample very small companies.³ We approximated this crudely by not sampling any companies below the \$10 million threshold. Analogous cost considerations motivated the geographical truncation: costs depend on distance from Princeton, NJ; benefits do not.

These two exclusions, however, might compromise the representativeness of the sample. So we remedied them as follows. Suppose pricing behavior varies geographically only because industrial structure differs across states, not because, say, California firms are inherently different from New Jersey firms. Then we can (and did) create a *synthetic national sample* by reweighting each firm in the Northeast to reflect na-

²Considerable effort was expended to guarantee the latter. For example, I abjured any questions that might conjure up images of the U.S. Department of Justice.

³This presumes that the study aims to explain the behavior of the GNP deflator.

tional, rather than regional, shares in value-added. Firms in industries that are overrepresented in the Northeast, like banking, were appropriately undersampled; and firms in industries underrepresented in the region, like gas and oil extraction, were correspondingly oversampled. Thus, the industrial structure of our sampling frame matches that of the nation as a whole.

While we were adjusting sampling weights, it was a simple matter to reduce the potential bias from omitting small firms. For example, any sample that excludes firms with annual sales under \$10 million will underweight retailing. We simply oversampled the remaining retail firms enough to assign retailing its proper national weight—and similarly for every other two-digit industry. In this way, we eliminate from our sample the portion of any “large-firm bias” that stems from the different industrial structures of small versus large firms. However, to the extent that small firms really differ from large firms *in the same industry*, the bias remains.

IV. Preliminary Results

The interviewing is now in progress. Given the limited clerical and interviewer resources at my disposal, we are conducting them in eight waves of approximately 50 letters (25 interviews) each over a period of about 18 months. As of this writing, the first three waves are nearly complete and we have just begun the fourth.

The results reported here are based on tabulations of the 72 interviews completed as of mid-November 1990. Since this partial sample is too small to permit much useful disaggregation, I restrict my attention to national averages here. Once the full sample of 200 is available, however, there will be a great deal of information about, for example, how the validity of different theories varies by industry.

The questionnaire comes in two parts and usually takes about 45–60 minutes to administer. The first part gathers a variety of factual information about each firm, while the second inquires directly about the theories. The factual data will eventually be

TABLE 1—MEASURES OF PRICE STICKINESS^a

A. Frequency of Price Change ^b		Percent of Companies
More than 12		10.1
4.01 to 12		4.3
2.01 to 4		10.1
1.01 to 2		20.3
1.0		37.7
Less than 1.0		17.4
B. Question: How much time normally elapses after a significant _____ before you raise (reduce) your prices?		
Event	Mean Lag ^c	Standard Deviation
Increase in demand	3.23	2.93
Decrease in demand	3.60	3.93
Increase in costs	3.17	2.90
Decrease in costs	3.97	4.47

^aBased on 72 interviews completed as of mid-November 1990.

^bTimes per year.

^cIn months.

used for disaggregation, in cross tabulations, and as right-hand variables in regressions explaining the validity of the various theories. I make little use of these data in this paper, but one issue is important enough to deal with right now: Just how “sticky” are prices in the U.S. economy?

To find out, we ask each firm, “How often do the prices of your most important products change in a typical year?” The distribution is shown in panel A of Table 1. These results offer cheer for Keynesians who model prices as, say, rigid for one period or more. I like to joke that in macroeconomic theory we know that the length of “the period” is one quarter. According to these data, less than 15 percent of the GNP is repriced more frequently than quarterly, and fully 55 percent is repriced no more often than once per year. If we had to pick a single abstraction to represent the whole economy, annual price change (the median response) would appear to be the “right” model.

From the point of view of macroeconomic theory, frequency of price change may not be the right question to ask, for it depends as much on the frequency of shocks as on

firms' pricing strategies. We are more interested to know how long price adjustments lag behind shocks to demand and cost. Panel B summarizes the results from a series of questions of the form, "How much time normally elapses after a significant _____ before you raise [reduce] your prices?" We inquire about four events: an increase in demand, a decrease in demand, an increase in cost, and a decrease in cost. The table shows that, while the distributions are quite spread out, the mean lags cluster in the 3–4 month range. There is precious little evidence that prices increase faster than they decrease, and virtually none that firms respond to cost shocks more quickly than to demand shocks.

The bulk of the questionnaire inquires about the twelve theories themselves. We begin each section by succinctly summarizing one of the theories and then posing a question like, "How important is this in explaining the speed of price adjustment in your company?"⁴ Respondents answer freely in their own words, but interviewers code the responses on the four-point scale indicated at the bottom of Table 2.

While the scale resembles the typical grading system used at universities, we should expect the "grades" to be more compressed. At the high end, no theory is ever going to score a perfect 4.0. A theory rated "very important" by half the firms and "of minor importance" by the other half would be a fine theory indeed. So I would interpret a score of 3.0 as excellent. At the low end, a score of 1.0 would mean that every firm in the sample dismissed the theory out of hand. This is not a grade of D, but a kind of super F. Indeed, any score below 1.5 is a remarkably poor performance.

If the respondent says a particular idea is "totally unimportant" to the speed of price adjustment, we ask no further questions about that theory. Otherwise, we ask a variety of follow-up questions (sometimes many,

TABLE 2—SUMMARY EVALUATION OF THEORIES^a

Rank	Theory	Mean Score ^b	Percentage "3" or Higher
1	Delivery lags/ service	2.86	65
2	Coordination failure	2.85	66
3	Cost-based pricing	2.72	57
4	Implicit contracts	2.52	56
5	Explicit nominal contracts	2.29	40
6	Costs of price adjustment	2.28	43
7	Procyclical elasticity	1.97	36
8	Pricing points	1.97	33
9	Inventories	1.72	28
10	Constant marginal cost	1.56	19
11	Hierarchies	1.54	18
12	Judging quality by price	1.45	12

^aBased on 72 interviews completed as of mid-November 1990.

^bBased on the following scale: 1 = totally unimportant; 2 = of minor importance; 3 = moderately important; 4 = very important; N = don't know or cannot answer.

sometimes few) geared specifically to each theory. In this interim report, I ignore follow-up questions and concentrate on the main questions about the perceived validity of each theory.

Table 2 summarizes the central results on the validity of the twelve theories, as perceived by actual decision makers, ranked in order of popularity. The second column names the theories briefly, and sometimes cryptically. (Explanations follow.) The third column records the mean score on the four-point scale; remember that we expect most theories to score in the 1.5–3.0 range. We can interpret a rating of 1 or 2 as meaning that the firm rejects the theory as an explanation of price rigidity, and a rating of 3 or 4 as meaning that the firm accepts it. So the fourth column gives the percentage of respondents that rate the theory as 3 or higher—an indicator of the fraction of the private, for-profit GNP to which this theory

⁴For many theories, there is a preliminary factual question. For example, before we ask whether judging quality by price deters price increases, we first ask whether the firm thinks its customers actually do judge quality by price.

applies. The two alternative ways of ranking the theories agree closely. Ranked from best to worst by mean score, the theories are:

1) *Delivery lags / service*:⁵ The idea here is that price is but one of several elements that matter to buyers. Rather than cut (raise) prices when demand is low (high), firms might prefer to shorten (lengthen) delivery lags or provide more (less) auxiliary services. The mean score for this theory so far is a healthy 2.86. Seventy-six percent of the firms accept the premise, and 65 percent say it is an important factor in slowing down price adjustments.

2) *Coordination failure*: This very old idea has been revived and formalized in recent New Keynesian theorizing. The notion is that firms might like to raise or lower prices, but hesitate to do so unless and until other firms move first. Once other firms move, they follow quickly. The mean score for this theory of 2.85 and its "acceptance rate" of 66 percent are quite high indeed.

3) *Cost-based pricing* connotes another old Keynesian idea: that prices are based on costs and do not rise until costs rise. Well over half the firms in our sample so far rate this a moderately or very important factor in explaining the speed of price adjustment; the mean score is 2.72.

4) *Implicit contracts* connotes the "invisible handshake" theory that firms have implicit understandings with their customers which proscribe price increases when markets are tight. Though this theory obtains an average score of 2.52, it elicits strikingly bimodal responses. Sixty-one percent of the sample accepts the premise that implicit contracts exist and, within this subsample, respondents generally think such contracts are an important source of price stickiness: the mean response within this group is a stunning 3.42.

5) *Explicit nominal contracts* refers to the naive Keynesian idea that written contracts prohibit price adjustments while they remain in force. Most firms have such con-

tracts, for at least some of their products; but discounting appears to be common. Our rough estimate is that this is an important factor in price stickiness for only about 40 percent of the economy. The mean score (counting firms with no explicit contracts as 1's) is 2.29.

6) A number of theorists have suggested that firms incur special *costs of price adjustment* whenever they change prices. Both menu costs and convex costs are lumped together under this rubric, but follow-up questions distinguish between the two. About 70 percent of all firms report that they have such costs. But fewer than half think them an important factor in slowing down price responses. The average score is 2.28.

7) According to a very old idea revived in the mid-1980's, demand curves become less elastic when they shift in. Such *procyclical behavior of elasticity* would lead to countercyclical markups which would, in turn, rigidify prices. This is another case where the premise is often accepted (59 percent of the time), but the idea is thought to be a significant source of price rigidity in only 36 percent of the cases. The average score is just below 2, which connotes minor importance.

8) *Pricing points* refers to the idea that certain prices (such as \$19.95 for a shirt) are psychological barriers that firms are reluctant to cross. This also scores 1.97 on average. Again, a majority of the firms (53 percent) accepts the premise; but only a third think it explains much price stickiness.

9) *Inventories* refers to the theory that, when demand rises (falls), firms draw down (build up) their inventories rather than increase (decrease) prices. Note that this question is not asked of service companies, so the sample size so far is only 33. Of these, however, fewer than a third think inventories a significant factor in deterring price adjustments. The average score is a low 1.72.

10) *Constant marginal cost* is shorthand for the notion that prices are sticky because both marginal costs and markups are constant over the business cycle. Since its ratings are so poor (a mean score of only 1.56

⁵Space constraints prohibit me from giving scholarly references for each of the theories. I apologize to those slighted.

and an acceptance rate of just 19 percent), I should explain how we posed the question. First, we asked respondents how their "variable costs of producing additional units" (our plain-English translation of marginal cost) behave as output rises. Only 42 percent of the sample reported that their MC was constant. Among this minority, about 60 percent said that the constancy of MC was totally unimportant or of minor importance in explaining their speed of price adjustment.

11) *Hierarchies* is a code word for a "theory" that does not come from the academic literature. Rather, it was suggested to us by an executive of a large corporation. The simple idea is that price changes are slowed down by the difficulty of getting a large, hierarchical organization to take action. Its low average score of 1.54 may appear unsurprising, since it should apply only to giant companies. But, even among firms with annual sales over \$100 million, its mean score is only 1.66.

12) The worst theory, according to our practitioners, is *judging quality by price*, a theory I have mentioned before. It obtains a paltry mean score of 1.45 and an acceptance rate of just 12 percent. Less than a quarter of the firms in the sample so far think their customers would "interpret a price cut as a signal that the quality of the product has been reduced." In our tabulations, we count the others as rating the theory "totally unimportant." However, among the minority of firms whose customers *do* judge quality by price, roughly 45 percent say it is a moderately or very important factor in dis-

couraging price increases. Thus this theory may be of some importance within a narrow sector of the economy.

In summary, it seems to me that the theories divide themselves into three groups. The top four listed above distinguish themselves as especially promising and/or applicable to the U.S. economy. The leading theory (by a slim margin), delivery lags/service, has not received the attention it deserves. The other three look to me decidedly Keynesian. Cost-based pricing is, of course, old-fashioned Keynesian stuff. Coordination failure is a major strain of New Keynesian theorizing. And the "invisible handshake" is by now part of the Keynesian tradition.

At the bottom of the list, we find four theories that appear to be rejected by our respondents. Two of them have enjoyed great popularity in the 1980's. If practitioners are to be believed, marginal costs are constant in only a minority of industries. And judging quality by price appears to be neither a common nor an important phenomenon.

It is true that these results are based on only 36 percent of the ultimate sample. But I will be surprised if the rankings change dramatically as more data come in; 72 observations is sufficient to answer most questions about national averages. The payoff to a large sample will come later, when I have enough data to answer disaggregated questions like, "What kinds of firms make 'invisible handshakes' with their customers?" I will report information of that sort at a later date.

DISCUSSION

ROBERT J. SHILLER, Yale University: This is exciting research. Theories of price stickiness are fundamental to much of macroeconomics. Surely it is a good idea to let those who set prices explain why they do what they do. These people tend to be professionals who have reason to think carefully about their reasons. Alan Blinder has done a very creative job of finding out what they can tell us. I hope that this is the beginning of many studies that use similar methods.

Blinder is working here to rectify the damage that overliteral interpretation of Milton Friedman's theory of positive economics has wrought in the economics profession. Many people seem to have thought that Friedman's "billiard player" analogy justifies omitting ever asking people about what they do. Friedman may be right that one cannot ask the player to explain why some shots are effective, and that a theoretical physicist could explain better. But, on the whole, I think that it would be a disastrous mistake to ask a physicist to model the behavior of a billiard player without allowing the physicist to get the player's help in the modeling process. The physicist will not understand the strategy of the game, will not know what the player's short-run objective would be on a given shot, and will likely omit considerations such as english or margins of error that may be difficult to theorize about or about which the physicist does not have full information.

The whole premise of the billiard player analogy that we economists should assume that people know how to optimize is also wrong. In many of the important economic decisions people make, such as the decisions on pricing strategy discussed here, a real evaluation of the outcome is not possible for many years, and even then the long-run effects cannot be disentangled from many other factors that are changing through time. Lacking such evaluations, people must satisfy or imitate successful people. There are hunches or popular models of the world that guide people, and we had best find out what these are:

Instead of "positive economics" as that term is commonly interpreted, we should instead follow what Edward Leamer calls "Sherlock Holmes inference," looking at every scrap of evidence and being alert to the evidence that even "small" or "unreliable" clues provide. Fortunately many economists seem to heed Leamer's advice, but the evidence obtained by asking people about the reasons for their behavior is not commonly used.

The research presented here should provide a good launching pad for further work in the future. As a pioneering study, Blinder's paper takes a broad view; much refinement should follow.

I was struck that the number one theory (the theory that delivery lags and service vary instead of price) may not be so much a theory of price rigidity of interest to macroeconomic theorists as it is a theory that the prices we *measure* are more rigid than true prices, particularly if we consider the service cuts part of this theory. If, instead of raising a price, a firm imposes costs on the buyer in the form of declining service, so that the buyer must pay for this service somewhere else, then the "true" price has changed, no "excess demand" should be generated by the failure to raise the nominal price. Thus, further research might ask decision makers directly why they sometimes allow a situation of excess supply or demand to persist, rather than asking about price rigidity *per se*.

We could also adjust our research strategy to try to understand why the standard business practices survive as they do, through time and against the occasional testing by innovators. To learn about this, it would be good to ask price setters about actual experiments that were made in *changing* price-setting behavior. Ask them to remember any story about someone who tried arguing for a different policy. Track that person down, and get the story as to what lessons were learned from the experience. Doing this is perhaps much better than asking the current price setters themselves, who might only report the vaguest

recollections of the outcome of past experiments.

Further research might also clarify the importance of fairness considerations in price-setting behavior. About half of Blinder's twelve theories might be interpreted as relating to concerns about possibly unfair behavior of price changers; indeed a number of questionnaire items concern whether they think the behavior would "antagonize" customers. Further attention could be focused on these questions. It seems likely that some rigidity of retail prices is due to such attitudes on the part of consumers.

Subsequent studies along lines initiated by Blinder might each focus in on one of the twelve theories, and spend more time eliciting information from respondents about the relevance of these theories. Respondents cannot give their full information about any of these theories without time to think and without substantial prodding. Much could also be learned by comparing answers to questions such as these across countries or through time. I think that it would be a good idea to supplement this endeavor with a similar survey of individual consumers. Their behavior is as important in many of these stickiness questions as that of price setters. There is a lot more work to do along lines suggested by Blinder's study, but this promises to be an excellent start.

ROBERT J. GORDON, Northwestern University: Alan Blinder's project is refreshingly novel. Instead of proposing yet another theory of price stickiness, he suggests that interviews with business people will prove the decisive filter to sort the theories. Although my own research predisposes me to sustained applause, I am happier with the point of departure of Blinder's project than with its detailed execution. To be fair, the critic cannot just append a list of additional questions that Blinder should have asked the respondents. As economists, we must treat interviewing time as a scarce resource. With the same 45 minutes or an hour, what would we have done differently?

My objections are fourfold. First, I question the basic approach of running a beauty

contest among theories, because there are too many overlaps among the poorly defined alternatives that are thrown at the respondents. For instance, a typical firm may adjust service and delivery lags, experience coordination failure, and base prices on costs, indicating that the most popular "theories" are complementary, not mutually exclusive. Second, Blinder exaggerates the degree to which the competing theories are "empty", and misses a unique opportunity to distinguish among theories by probing deeper. Third, many of the questions are vulnerable to the failure to specify time dynamics carefully. Fourth, although the project is spaced out over two years, there is no "funnel" principle by which early results lead bad theories to be discarded, so that the released time is used to probe more deeply into the good theories.

Here's an alternative approach that would have yielded more out of the same interviews. For price stickiness to matter for business cycles, we must observe a failure of the aggregate price level to mimic fluctuations in nominal GNP. To use this notion to sort theories, we can introduce the four-way distinction among aggregate and local demand and supply shocks. Then we would ask respondents how much they would change price over a specified period after a specified event involving one or more of the four shocks.

For instance, we might ask hypothetically what happens to price if nominal GNP drops by 5 percent but the firm's revenue and costs do not change. If the respondents answer that no price change is warranted, then we have important evidence to bolster the old micro truism that firms care about the relation of price to cost, not price to nominal GNP. Then we might ask, when nominal GNP drops by 5 percent, why don't you assume that your costs will drop by 5 percent? If not now, over what horizon? This would tell us something about the underpinnings of coordination failure, and what I call the input-output table approach. We then might ask hypothetically what happens to price if aggregate and local nominal demand rise by 5 percent, while costs are constant, versus an opposite situation in

which costs rise by 5 percent while local and aggregate demand remain constant.

If the respondents say in the fashion predicted by Okun that they raise price more in response to costs than demand, we could then ask them about menu costs. I would ask every firm why they change prices infrequently, while the price of avocados and navel oranges can change daily. What's the crucial difference between them and the produce department of the local supermarket? One could ask each firm why it changes price so infrequently—is it that menu costs are so high, or that demand and/or costs change at such a steady and predictable rate? How much would demand and/or costs have to jump to cause the firm to break out of the annual pattern and move to shorter intervals of price changes (we know, after all, that prices change much faster in Brazil than in the United States). Throughout this investigation, one would want to dig beneath the trite but true explanations 2 and 3 in the Blinder ranking (coordination failure and cost-based pricing) to ask why firms fail to coordinate, why they do not change price to mimic nominal GNP, why they fail to assume costs will not mimic nominal GNP, and whether they react instantly to every cost change or lump the reaction to cost changes into a single infrequent price change, and why.

Since the emphasis of Blinder's paper is on the virtues of interviews and on survey design, it is helpful to recall the most famous antecedent of his project, the famous 1939 study by Hall and Hitch. Their classic paper is a good model to suggest changes in Blinder's approach. Instead of conducting a popularity poll, they start with a single theoretical point of departure for the questions, the standard theory that marginal cost should equal marginal revenue, and then, building on the discovery that full rather than marginal cost matters, ask why so? They come to a profound conclusion that has been the basis for much Keynesian thinking since 1939, "prices... will be changed if there is a significant change in wage or raw material costs, but not in response to moderate or temporary shifts in demand" (p. 33). Is this still so, and if so, why?

HERSCHEL I. GROSSMAN, Brown University: Properly designed interviews can be valuable sources of information about how people behave. But, the ability of interviews to reveal why people behave as they do (or, more precisely, to discriminate among different models of decision making) is more problematic. Alan Blinder's defense of his interview survey against possible methodological criticisms does not recognize this distinction between the gathering of facts about behavior and the explaining of facts about behavior. This failure reflects what seems to me to be Blinder's underlying ambiguity about his objectives and about what he means by a "theory" of price stickiness.

When we speak of a theory about economic behavior, we usually have in mind a connected set of assumptions and derived implications about the decision-making process of economic agents. In neoclassical economics, these assumptions involve a specification of preferences and constraints and the derivation of implications involves the solution of a constrained-maximization problem. As we can interpret any behavior that we observe to be the solution to some constrained-maximization problem, a central part of the research program of neoclassical economics that we as neoclassical economists are trained to carry out is an attempt to discover the particular constrained-maximization problem that best fits the facts. Because the facts with which economists are concerned typically involve observations about markets or economies, rather than about the idiosyncratic behavior of specific individuals, we are usually satisfied if a theory fits the facts in an "as-if," rather than literal, sense.

With a couple of possible exceptions, the twelve "theories" of price stickiness that Blinder sets out are not theories in the sense of models of decision making. Blinder's theories are mainly hypotheses about how people behave rather than about why they behave as they do. Accordingly, most of the information that his interviews elicit does not directly address the neoclassical question: What specifications of preferences and constraints are likely to be useful for building constrained-maximization

models of price setting that are empirically relevant?

One possible exception to the criticism that Blinder's theories are not attempts to explain behavior is the theory that he denotes "coordination failure." Theorists have formulated coherent models in which difficulty in coordinating strategies constrains price changes. But, the questions that Blinder poses to his interviewees do not seem to get to the factors that distinguish such theories. Specifically, the unsurprising fact that most firms report that "they are afraid to get out of line with what they *expect* competitors to charge" (emphasis added) does not by itself imply that coordination problems actually impede price adjustments.

The other possible exception to my criticism of Blinder's theories is the theory that he denotes "cost of price adjustment." It is interesting to know that "fewer than half" of the interviewees report that costs of price adjustment are an important constraint on pricing decisions. But, even so, such a constraint might still be a useful component of a model that is true in the as-if sense.

Blinder's other theories, especially the ones he denotes "delivery lags/service," which receives the highest score from his interviews, "cost-based pricing," as well as the ones he denotes "implicit contracts" and "explicit nominal contracts," describe the results of interactions between buyers

and sellers, but do not address why buyers and sellers behave as they do. Delivery lags, cost-based pricing, and contractual arrangements, whether implicit or explicit, are symptomatic of underlying preferences and constraints. For example, delivery lags and/or contracts might be symptoms of coordination failure or of adjustment costs. Theories that attempt to explain behavior would specify the preferences and constraints that lead to delivery lags and cost-based pricing, or that produce the choices that are codified in contracts.

One final constructive criticism: I strongly endorse Blinder's view that "Keynesian economics is...the economics of nominal rigidities." The distinctive emphasis on the stickiness of nominal wages and prices and on the associated possibility that monetary disturbances can cause markets to fail to clear explains why Keynesian economics remains central to the modeling of macroeconomic phenomena. For this reason, I would have liked Blinder's survey to have included questions that would have distinguished between nominal and real rigidities.

In sum, Blinder's interviews provide information about pricing behavior, but little or no information about the reasons for this behavior. Is the problem that interviews are not capable of addressing the questions to which we really want answers? Or, has Blinder not yet fully exploited the interview methodology?

Projecting Faculty Retirement: Factors Influencing Individual Decisions

By G. GREGORY LOZIER AND MICHAEL J. DOORIS*

The impending elimination of mandatory retirement for tenured faculty on January 1, 1994 (Public Law 99-592, 1986), has raised the visibility of a number of questions about faculty retirement behavior. What are the factors that influence individual faculty members' retirement decisions? How important are financial and nonfinancial considerations? Why do faculty in private institutions work to a later age, on average, than their colleagues in public institutions? Are there other systematic (for example, gender- or discipline-related) differences as well?

This paper is an attempt to answer such questions about individual faculty retirement behavior. The paper utilizes data collected as part of a comprehensive national study that projected faculty retirements through the year 2003 for over 35,000 faculty at 101 doctoral research, comprehensive, and general baccalaureate institutions (see our 1990 paper). The discussion that follows uses data from that broader institutional survey and from a survey of 747 faculty members age 55 and over who had separated from this same set of 101 institutions. Among the information provided by the 518 usable responses were data on factors that influence faculty members' decisions regarding the appropriate time to retire.

I. Factors Influencing Retirement Decisions

Previous Studies. Some higher education studies have touched on individual faculty

retirement behavior, but much of what is known is drawn from research in other employment sectors. For example, an empirical study by H. Anderson et al. (1986) determined that the retirement decision among the general workforce is influenced by both the current value of relevant variables such as income, inflation, and health, and by expectations about their future value. They found that retirement decisions within the general work force are most likely to be altered by changes or anticipated changes in such factors as Social Security benefits, recession or inflation, unemployment rates, and rates of economic growth. This finding reinforces the results of an earlier report by S. F. Quinn and R. V. Burkhauser (1983) in which they found that financial considerations such as Social Security benefits were critical factors influencing retirement decisions. Similarly, S. LaRock (1987) noted that, in addition to such determinants as health, workplace interaction, and intensity of family ties, perceived adequacy of retirement income and the financial status and retirement plans of one's spouse were the most critical elements influencing the retirement decision.

In the higher education sector, among the major findings of three studies conducted for the Consortium on Financing Higher Education (COFHE) was the observation that the most powerful predictor of delayed retirement was "fear of inadequate income during the first two years of retirement" (S. Montgomery, 1989, p. 57). The most frequently cited reason for postponing retirement, as reported in one of the studies, was the need for continued full-time salary.

Study Results. The present study used 18 factors of potential influence on the retirement decisions of faculty members. These factors were derived from those iden-

[†]*Discussants:* W. Lee Hansen, University of Wisconsin-Madison; Olivian Mitchell, Cornell University.

*Executive director and senior planning analyst, respectively, Office of Planning and Analysis, Pennsylvania State University, University Park, PA 16802.

tified in the studies cited above as being important to the general workforce. In the survey, respondents indicated on a Likert scale the extent to which each of the 18 factors was not important (1) or very important (6) in their decisions to retire. The factors and their average ratings (in parentheses) were:

1) Overall financial status (4.4); 2) Eligibility for full retirement benefits (4.4); 3) Desirability of more personal/family time (4.1); 4) Other interests (3.5); 5) Working conditions and policies (2.9); 6) Availability of early retirement incentive benefits (2.6); 7) Personal health (2.5); 8) Annual salary increases (2.2); 9) Availability of emeritus benefits (2.2); 10) Mandatory retirement policies (2.1); 11) Other employment opportunities, including self-employment (2.0); 12) Health of a spouse (1.9); 13) Administrative pressure (1.8); 14) State of the economy (1.8); 15) Interaction with coworkers (1.7); 16) Budget cutbacks (1.7); 17) Curricular revision (1.6); 18) Timing of spouse's retirement (1.5).

Every factor received ratings at both extremes of the scale. In other words, each was important to some respondents and not important to others. Even so, the two most salient factors emerging from the responses were overall financial status and eligibility for full retirement benefits. In addition, the availability of early retirement incentive benefits, while not an important variable (and perhaps unavailable) to 60 percent of the respondents, was the most important factor in the retirement decision for over 20 percent of the faculty retirees. When such programs are available, they become a powerful variable in combination with other financial considerations.

Some distinctions were identified when the ratings were analyzed by discipline and gender. Statistically significant relationships between the retirement factors and discipline were found for four factors: 1) desirability of more personal/family time; 2) working conditions and policies; 3) state of the economy; and 4) budget cutbacks. Education faculty were more likely to see the need for more personal/family time and the state of the economy as more important factors in the retirement decision

than faculty in other disciplines. Agriculture faculty were more likely to make the retirement decision based on working conditions and policies and budget cutbacks. Library sciences faculty were also more likely to consider working conditions and policies in their retirement decisions. Although the "other employment opportunities" factor did not produce an overall significant difference by discipline, it was interesting to note that all library sciences faculty retirees responded to this item with a minimum score of 1.0, that is, not important.

Separate analyses of the retirement decision factors by gender also identified four statistically significant variables: 1) other interests; 2) working conditions and policies; 3) administrative pressure; and 4) interaction with coworkers. The greatest variability between male and female responses on these four factors was on working conditions and policies (2.8 vs. 3.4). The average rating for "other interests" for both females and males was 3.5. However, the male responses clustered around the average, while those of the females tended to be at one extreme of the ratings scale or the other.

It is important to reiterate that, even when there were statistically significant differences by either discipline or gender, financial considerations were still the predominant factors in the retirement decision.

II. Impact of Retirement Program Type on Retirements

One determinant of "overall financial status" in retirement is the income replacement value provided by an individual's retirement plan annuity. Most retirement plans in higher education are one of two types: defined-benefit or defined-contribution programs. Defined-benefit plans are typical of state employee retirement systems while defined-contribution plans are associated more with private retirement programs, the best known of which is TIAA-CREF. According to F. P. King and T. J. Cook:

[T]he *defined benefit* approach fixes benefits in advance as a percentage of salary for each year of service or, as in

some industrial plans, a flat dollar amount per month or year of service. The *defined contribution* approach fixes contributions in advance as a percentage of each employee's salary, allocates these contributions to individual accounts, and pays benefits on the funds credited to each participant.

[1980, p. 44]

In short, the former fixes benefits, while the latter fixes contributions.

A number of studies on faculty retirement trends have established a relationship between institutional control, that is, public vs. independent, and average age of retirement (Consortium on Financing Higher Education, 1987; W. L. Hansen and K. C. Holden, 1981; our 1988-89 article and 1990 paper). These studies have shown that the faculty retirees in independent institutions are, on average, two to three years older than their peers in public colleges and universities. Although multiple factors likely contribute to this difference, there has been some speculation that one of these may be type of retirement program.

How likely is it that the public-private retirement age difference is related to the defined benefit-deferred contribution distinction? The evidence is mixed. Holden and Hansen, noting the difference in retirement trends between public and independent institutions, have developed cost analyses to assess whether type of retirement program may be one of the multiple factors influencing differences among institution types. In their model they observed that "despite very different plan structures, annual benefits from defined-benefit and defined-contribution plans increase comparably, on the average, as retirement is postponed" (1989, p. 79). They concluded that the decision to defer retirement is not likely to be caused by enrollment in one type of plan.

A recent TIAA-CREF *Research Dialogues* (1990) explored the issue further using a measure called the "salary replacement ratio." This is simply the ratio of retirement income to preretirement salary. Examining two different scenarios, one in which the individual enters the retirement plan at age 30 and another in which the

individual enters the retirement plan at age 45, the analysis looks at the salary replacement ratio for retirement at ages 65 through 70, for both defined-contribution and defined-benefit plans. The TIAA-CREF analysis reveals "that a delay of retirement beyond normal-age 65 can be expected to provide somewhat higher initial benefits in subsequent starting years under both the defined contribution and defined benefit plans" (p. 5). However, the average replacement ratio under the defined-benefit plan is approximately 9 percent lower than the defined-contribution program.

Retirement Plan Retirement Age Differences. The present study did not attempt to model actual retirement benefits derived from defined-benefit and defined-contribution programs. The study was set up to collect data on age at retirement by institutional control and type of retirement program. In particular, the institutional survey segment of this study (101 responding institutions) was geared in part to the question of whether the type of retirement program had any relationship to average age of retirement. In order to separate the institutional control effect on type of retirement program, separate average retirement age calculations were developed for all retirees in each of four clusters:

Public defined-benefit retirees, 63.1 ($n = 475$); public defined-contribution retirees, 65.4 ($n = 580$); independent defined-benefit retirees, 65.4 ($n = 6$); independent defined-contribution retirees, 65.3 ($n = 1241$).

The average retirement age among public institution retirees is over two years lower, 63.1 vs. 65.4, for defined-benefit retirees. The 65.4 average retirement age for public defined-contribution retirees is also extremely close to the higher 65.3 average age for independent defined-contribution retirees. (Because so few independent institutions offer defined-benefit programs, there were only 6 independent defined-benefit retirees, a number too small from which to draw any conclusions.)

Explaining the Difference. Although the data presented above do not establish a direct cause and effect relationship, the results suggest some interactive effect be-

tween type of retirement program and the retirement decision. However, it is not clear that in all cases early retirement is more likely under one type of plan than the other.

Both the Holden-Hansen and TIAA-CREF analyses discussed above point out that defined-contribution and defined-benefit plans are designed to produce fairly comparable levels of retirement income for individuals with similar years of service and income history. Yet, the TIAA-CREF discussion also points out that at some point future retirement income increases more rapidly under the defined-contribution program. "Return on investment" is a useful concept for examining further whether under this circumstance one type of plan is more likely to encourage earlier or later retirement.

The *investment* would be the additional years worked beyond "normal" retirement age, while the *return* would be measured as the additional retirement income. In the case described in the TIAA-CREF *Research Dialogues*, retirement income for working beyond age 65 increases more rapidly under the defined-contribution program than under the defined-benefit plan. Assuming, on the one hand, that the prospective retiree has established a desirable retirement income level necessary to trigger the decision to retire, the defined-contribution participant could achieve this level sooner than a defined-benefit participant. Under this scenario, the defined-contribution plan would provide a good return on the investment of additional years of service and would encourage an earlier retirement, as the prospective retiree meets the preset retirement income goal sooner than would have been realized under the comparable defined-benefit plan.

On the other hand, the slower post-65 replacement ratio growth rate under the defined-benefit plan could encourage the participant to retire earlier *if* the employee determined that the amount of increase was not sufficient to warrant continued employment, that is, the marginal return was not worth the investment of each additional year worked. The latter factor could help to explain why participants in some defined-benefit plans have suggested that they re-

tired when they did because they would have "continued to work for free." To the extent that defined-benefit programs have provisions that eliminate penalties for retiring after 30 or 35 years of service, or have other provisions that limit or reduce the rate of growth in anticipated retirement income, this latter scenario may contribute to the explanation for the younger retirement age for faculty members on defined-benefit annuities.

III. Discussion

In the face of the impending elimination of mandatory retirement in 1994 for all colleges and universities that have not already done so, institutions have shown considerable interest in devising mechanisms for influencing retirement rates. Because of the importance of individual financial status upon the retirement decision, financial inducements are probably the most powerful tool for influencing that decision. In fact, a financial response in the form of incentive early retirement programs was the initial reaction of many institutions in the late 1970's and 1980's as the permissible mandatory retirement age shifted from 65 to 70 (J. L. Chronister and T. R. Kepple, 1987). Whether incentive early retirement programs are the correct response in light of more recent information regarding faculty age distributions and anticipated retirement rates has been the subject of debate. It is questionable whether incentive programs that become permanent or are available to all prospective retirees produce the desired effects. There is speculation that the more useful programs have been those that have been limited in both duration and scope. Institutions may wish to analyze correlations between retirement income and retirement age to determine the likely effect of incentive programs or other measures.

Beyond confirming the importance of financial considerations, this study suggests that virtually all factors that bear upon the retirement decision are relevant to some faculty but not to others. Retirement is a very personal decision. Variables such as the faculty member's health or the health of a spouse, other professional consulting and

employment opportunities, and the need for more personal time cannot be controlled by the institution. Similarly, budget cutbacks at the state or federal level, inflation and recession, or changes in Social Security provisions are outside the realm of institutional policy.

But other factors, including several that differ significantly in importance among faculty on the basis of discipline and/or gender, can be influenced by the institution. For example, working conditions and policies make a difference in the retirement decisions of library science faculty and of women. Women also noted that administrative pressure and interaction with coworkers affect the desirability of continued employment.

Finally, the results of this study clearly showed that, perhaps as expected, money, as a factor in the retirement decision, matters to nearly everyone. The effects of less tangible elements of professional satisfaction are not as uniform or consistent, but nonetheless they matter also. Career and retirement decisions are ultimately individual decisions, and the significance of personal interactions, the work environment, leadership, and so on cannot be discounted. The extent to which deans and department heads can recognize and act upon the full range of financial and nonfinancial variables is of critical importance in influencing personal career and retirement behaviors of faculty members.

Ending Mandatory Retirement in the Arts and Sciences

By SHARON P. SMITH*

No institution interested in preserving quality can tolerate a growing gerontocracy that necessarily brings with it declining productivity. The disastrous effect on young scholars surely needs no elaboration. If ever mandatory university retirement is deemed to be age discrimination, an alternative mechanism will have to be found to accomplish the same purpose.

[Henry Rosovsky, 1990, p. 211]

On January 1, 1994, the elimination of mandatory retirement for tenured faculty (uncapping) which was enacted in the 1986 amendments to the Age Discrimination in Employment Act (ADEA) will take effect. This grace period between enactment and effective dates was a response to the concerns that have been regularly expressed by educational administrators such as Rosovsky. In the congressional debate concerning the impact of uncapping on the retirement behavior of tenured faculty and the implications of any behavioral changes for the vitality of higher education, it was concluded that this delay would allow time for study, adjustment, and the opportunity to request a permanent exemption, if necessary.

The concerns voiced by educational administrators have several dimensions. In the absence of a mandatory retirement clause, academic tenure becomes a lifetime employment contract. Under these conditions, the central concern is whether in a world in which all retirement is voluntary, no faculty

will volunteer. This anxiety raises concerns over the implications of such a change in behavior for: job opportunities for new faculty;¹ the success of affirmative action initiatives that call for the integration of women and minorities into a faculty population that was historically largely white male; the cost of predominately senior faculty in which each member is presumed to be relatively highly paid; and the quality of education provided by faculty whose abilities and whose timeliness of ideas may be diminishing with age.

The Project on Faculty Retirement (PFR) was established in response to these concerns.² It was sponsored by the American Association of University Professors, the Association of American Universities, the Consortium on Financing Higher Education, and the National Association of State Universities and Land Grant Colleges to analyze the implications of uncapping for tenured faculty in the arts and sciences.³

The PFR's research had three thrusts: an analysis of the current and estimated future retirement behavior of tenured faculty; an inquiry into the attitudes towards retirement among tenured faculty who have already retired and those who are nearing the age for a retirement decision (55 and over); and a study of the relationship between chronological age and a variety of indicators of faculty vitality (student teaching evalua-

¹With a growing consensus that higher education faces an imminent shortage of faculty for the arts and sciences, this issue has obviously declined in significance. See William Bowen and Julie Ann Sosa, 1989.

²The amendments to the ADEA also required a study of the implications of uncapping to be done by the National Academy of Sciences. However, that study was funded too late in the grace period to be able to conduct much quantitative research. The staff of the PFR and the National Academy study have communicated regularly to coordinate activities and reduce overlap.

³The full findings of the Project on Faculty Retirement are reported in Rees and my forthcoming study.

*Dean, College of Business Administration, Fordham University, Bronx, NY 10458. I draw freely from my joint work with Albert Rees. This research was supported by grants from the Andrew W. Mellon Foundation, the Carnegie Corporation of New York, and the William and Flora Hewlett Foundation. It also benefited from the expert research assistance of Jerene Good. I thank Rees for helpful suggestions on an earlier draft of this paper.

tions, articles and/or books published, research grants received, etc.) These analyses were based on two different sets of data. The first consisted of data on the current age of the tenured faculty and the flows into and out of tenure at a select set of institutions. The second consisted of a number of case studies and surveys conducted at a smaller number of institutions and surveys made by other organizations.

I. Format of the Study

I focus on the first concern of administrators: whether or not faculty will decide to retire when they are no longer required to do so. To analyze the impact of uncapping, however, it is necessary first to have a sense of faculty's current pattern of retirement. The PFR collected an original data set to do so. This data set was not, nor was it intended to be, a random sample. It consisted of data collected from a group of research and doctorate-granting universities and selective liberal arts colleges. It was designed to focus on the types of institutions in which either a change in retirement behavior was most likely to result from uncapping or a change in retirement behavior could lead to the most severe problems. The institutions where faculty were expected to delay retirement are prime research institutions. These are institutions in which faculty are most dedicated to research, the students are most qualified, teaching loads are light, and where active institutional association at least facilitates academic research and may be necessary for the research to occur at all. The institutions where delayed retirement could cause the greatest disruption are liberal arts colleges. These are institutions in which faculty sizes are so small that the presence of one faculty member who is incompetent could destroy the department.

Information was then gathered from thirty-three institutions (nineteen universities and fourteen liberal arts colleges) on the current age profile of tenured faculty (academic year 1988-89) by major discipline category (humanities, social sciences, and physical and biological sciences) and on the historical pattern of flows into (hire or pro-

motion)⁴ and out of (resignation, retirement, or death) tenure by discipline, type of flow, and age at the time of the flow. (Twenty-five institutions provided data for at least 5 years on all types of flows and the remainder provided data on retirements only.)

A number of states have already eliminated mandatory retirement by state law either for the tenured faculty in their state universities (for example, Connecticut, New York, Virginia) or for tenured faculty in all institutions of higher education (for example, Florida, Hawaii, Maine, Texas, Utah, Wisconsin) in their state. Wherever possible, data were collected for similar "capped" and "uncapped" institutions so that this "natural experiment" could be used to provide insight into the impact of ending mandatory retirement for all tenured faculty.⁵ Although some institutions uncapped very recently, others were uncapped for more than 10 years and can provide sufficient history to demonstrate whether or not the retirement decision changes when it is at the discretion of the faculty member. Data were gathered for tenured faculty in the arts and sciences only. (This limitation assured a more homogenous sample and was consistent with the primary interests of the PFR's principal source of funding.)

II. A Picture of Tenured Faculty

The data gathered on the current age distributions among tenured faculty in the sample provide a clue to the timing of when a change in retirement patterns (if it occurs as a result of uncapping) might be felt. The picture that emerges displays remarkable consistency regardless of type of institution, discipline, or capping status. The mean age

⁴In this context, "hire" signifies a hire with tenure to the institution in question and a "promotion" signifies an appointment to tenure at the institution from a previously untenured position. It should be noted that each of these flows represents a movement of individual faculty members into and out of individual institutions of higher education.

⁵There were insufficient selective private universities that were already uncapped to make this distinction for that category.

varies from 49.6 to 51.6. Although faculty are dispersed across an array of age cohorts, in most instances, they show the greatest concentration in the 46–50 age cohort. Thus the largest proportion of the tenured faculty is nearing but has not yet reached the age at which the retirement decision begins to come under consideration. Absent any move toward a permanent exemption from the ADEA for tenured faculty, they will make that choice voluntarily.

At the same time, the proportion of tenured faculty over age 70 is very small—0.7 percent in uncapped public universities is the largest.⁶ Moreover, less than 0.1 percent of all tenured faculty in the data set are over age 71. Indeed, in a data set of 8232 tenured faculty in all institutions, there are only 2 individuals who remain as active faculty members after age 75. The existence of a mandatory retirement law does not prevent the presence of active faculty beyond the mandatory age. The distinction is that in a capped environment, the decision to remain beyond the mandatory retirement age rests with the institution, whereas in an uncapped world, the decision to remain rests with the individual.

The proportion of faculty who choose to remain beyond age 70 depends in large part on the decisions that have been made at earlier ages. The 1978 amendments to the ADEA raised the mandatory retirement age for tenured faculty from 65 to 70 effective July 1, 1982. Thus sufficient time had elapsed for the faculty in this data set to have aged enough to take advantage of that change in the mandatory retirement age. Despite this opportunity, the proportion in the 66–70 age cohort ranged from 2.5 percent (capped liberal arts colleges) to 6.6 percent (private capped universities). Thus the proportion who will have the opportunity to choose to remain active beyond age 70 is likely to be quite small.

⁶The label of capped or uncapped pertains to the institution's status at the end of the period. Most of the institutions uncapped some time during the period of the data: one in 1976, one in 1978, three in 1980, three in 1984, one in 1986, and two in 1988.

Turning now to the data on flows, patterns emerge showing characteristic differences by type of institution. In liberal arts colleges, it appears that most faculty arrive early in their careers (without tenure) and if they subsequently receive tenure, they remain until retirement. In private universities, in contrast, faculty are nearly as likely to arrive with tenure as to be promoted to it. The pattern for public universities falls between these two.

An examination of the mean ages at which these events occur shows some surprising patterns. (However, the dispersion is such that none of the differences observed is statistically significant.) Hires with tenure, on average, take place at a later age (the early 40s) than promotions to tenure (the mid- to late 30s). Moreover, many hires take place at much later ages: in the private universities, 20 percent of these hires were age 50 or older. In fact, there are hires over age 60! These observations certainly call into question the assumption that retiring faculty would be replaced by newly minted, untenured, and relatively low-paid assistant professors. Indeed, an early retiree might be replaced by a newly hired but older and possibly more distinguished faculty member.

The data on retirement also show differences in mean age by type of institution. Mean retirement age at 66.8 is highest in private universities and lowest in liberal arts colleges at 65.3 for capped colleges and 64.3 for uncapped colleges—with public universities in between. There is generally little difference by discipline. In both public universities and liberal arts colleges, the mean age at retirement is generally slightly lower in the uncapped type.

The proportion of retirements at 70 or older also vary by institutional type and by individual institution within type. The proportion tends to be smallest in the liberal arts colleges (especially the uncapped ones, most of which show no late retirements) and largest in the private universities—where it is as much as 73 percent for one institution. Even within this institutional type, one institution had no late retirements and two had less than 5 percent.

TABLE 1—PATTERNS OF RETIREMENT
OF TENURED FACULTY

	(1)	(2)
Constant	-1.02 (-3.42)	56.23 (18.91)
SAT Scores per 100 Points of Combined Score	0.098 (4.14)	0.76 (3.24)
Research University	0.21 (4.11)	1.45 (2.84)
Formal Early and/or Phased Retirement Plan	-0.054 (-0.96)	-0.91 (-1.62)
Uncapped 5 years or More	-0.009 (-0.13)	0.014 (0.02)
Adjusted R-squared	0.56	0.40
No. Observations	31	31

Note: The *t*-values are shown in parentheses beneath regression coefficients.

Dependent variables: Col. (1) Proportion of retirements at age 70 or later; Col. (2) Mean age at retirement.

Regression analysis sheds further light on the differences in retirement ages. Results for two of the key regressions are displayed in Table 1. Each observation is an institution which provided 5 years of data on retirements. There were 31 observations used because not all data for all variables were available for all institutions. The dependent variable in the first regression is the proportion of retirements at age 70 or later (col. 1). Thus this regression does not address uncapping. Instead it provides insight into the determinants of "late" retirement. The dependent variable in the second regression is the mean age at retirement (col. 2). Thus this regression addresses the factors that tend to either postpone or expedite retirement.

The independent variables are the same for each regression. The first is the sum of the mean verbal and quantitative SAT scores of entering freshmen as reported in *Barron's Profiles of American Colleges* (1988). This variable is a direct measure of the quality of the students and an indirect measure of the quality of the institution. The variable is highly significant which suggests that professors are more likely to postpone retirement when they are teaching good students or are

in a good institution. The second independent variable takes the value one if the institution is classified as a research university,⁷ and zero otherwise. The coefficient of this variable is highly significant and of substantial size—suggesting that when a large part of a faculty member's job is research, retirement is likely to be postponed. Indeed these results suggest that the mean age at retirement is 1.45 years higher in research universities than elsewhere, all other things being equal. The third independent variable takes the value one if the institution has a *formal* early or phased retirement plan and zero otherwise. Although the coefficient of this variable has the right sign and is of substantial size, it is not significant at conventional levels—probably because of the small sample size. The fourth independent variable takes the value of one if the institution had no mandatory retirement age during the 5-year period covered by the data and zero otherwise. As expected, it has no impact in the first regression. The startling finding, however, is that this variable is zero and insignificant in the second regression as well.

These results suggest that tenured faculty retire later when their positions consist largely of research, their teaching loads are relatively light, and when they do teach, their students are good. Moreover, uncapping has had no perceptible effect on the mean age of retirement in selective liberal arts colleges and prominent public universities. Whether behavior might be different for private elite research universities or change over time in liberal arts colleges and public universities remains an open question.

In order to explore the implications of any change in retirement behavior in a totally uncapped world, the future composition of tenured faculties in each of the institutional types was projected using the

⁷This Carnegie classification includes those institutions that offer a full range of baccalaureate programs, give high priority to research, receive substantial federal support for research and development, and award at least 50 Ph.D. degrees a year.

Faculty Cohort Model⁸ and some very conservative assumptions concerning overall faculty growth and faculty retention rates—zero growth in the tenured faculty and a retention rate in the oldest cohorts that is 50 percent higher than that observed in currently uncapped institutions. The projections that result show little grounds for concern over a future dearth of opportunities for new faculty or for minority faculty. Instead the projections suggest an increase in the proportion of faculty age 40 or less by 2004, as other aspects of faculty demographics dominate any possible change in retirement behavior.

It appears, then, that there is little ground to suspect that large numbers of faculty will choose not to retire in a permanently and totally uncapped world. However, there is an exception to this conclusion: a few institutions that are presently still capped and whose faculty now tend to remain active until the mandatory retirement age of 70 will have substantial problems. In the PFR sample, these are elite private research universities.

There remains the concern, however, that the abilities of those who do remain will be much reduced with age. Here again there is little evidence to support this fear. Although research activity declines from mid-career, it does not cease. (See Alan Howe and myself, 1990.) The outlook for teaching effectiveness varies by discipline, but does

not suggest that age has a large effect in any case. (See Daniel Kinney and myself, 1989.) The evidence thus suggests that administrators' fears concerning the ending of mandatory retirement in the arts and sciences are largely groundless for much of higher education. The few faculty members who do choose to remain active beyond age 70 are unlikely to provoke questions of competence. Moreover, personnel policies can be designed that will encourage these faculty members to select retirement.

⁸This faculty planning model is a Markov Chain Model with feedback. The model was written by Rick Biedenweg and Tom Keenan for use at Stanford University. The Consortium on Financing Higher Education is making it available for use at any institution. See Biedenweg and Keenan (1989) for an explanation of the workings of this model.

The Effects of Pensions and Retirement Policies on Retirement in Higher Education

By ALAN L. GUSTMAN AND THOMAS L. STEINMEIER*

Exits through retirement are one of the important labor market flows that shape the age structure of faculty, and help to determine the quality and costs of higher education. As a result of perceived pressures from demographic changes, as well as in reaction to a series of policy initiatives, including a legal requirement that mandatory retirement be eliminated in higher education after 1993, institutions of higher education have become increasingly interested in predicting and influencing retirement behavior of faculty, while exerting more control over the associated costs of compensation.

Life cycle, structural econometric models of retirement have been used to analyze analogous policy issues at the national level (Gary Fields and Olivia Mitchell, 1984; ourselves, 1986a; Robin Lumsdaine et al., 1990). These models first specify and estimate the various components of the opportunity set. Then, based on the subsequent retirement behavior of those facing alternative opportunities, the parameters of the utility function that underlie the retirement decision are estimated. Once the components of a structural retirement model are estimated, effects on retirement outcomes of policy changes may be simulated (see our 1985, 1986b, and forthcoming articles).

In the present paper, we apply these techniques to analyze retirement behavior of the tenured, male faculty employed or retiring in the late 1970's at 26 member

colleges and universities of the Consortium On Financing Higher Education (COFHE), a group that includes some of the highest quality private colleges and universities in the country. The estimated model is used to analyze the effects of early retirement incentives and changes in mandatory retirement rules. Although the sample is not fully representative of higher education, and the data are over a decade old, these are the best data available for illustrating the usefulness of the recent developments in retirement research in analyzing related behavior and policies in higher education.

I. The Empirical Specification and Data

The utility function to be estimated is CES and is given by

$$U = (1/\delta) \int_0^T \{ [C(t)]^\delta + e^{X_t\beta + \varepsilon} [L(t)]^\delta \} dt$$

where $C(t)$ and $L(t)$ are consumption and leisure at time t , and T is the relevant time horizon; X_t includes age and a constant that affect the relative weight of leisure in the utility function at time t , and β is the associated vector of parameters, presumed to be constant across both time and individuals; δ (with $\delta \leq 1$) and ε are time-invariant stochastic terms reflecting, respectively, the elasticity of substitution between consumption and leisure for each individual and the relative weight that the individual places on leisure.

This utility function is maximized with respect to consumption and leisure, subject to the lifetime budget constraint

$$\int_0^T e^{-rt} \{ y[L(t), t] - C(t) \} dt = 0$$

where $y[\cdot]$ is the function relating compensation to leisure (and hence to work effort), and r is the real interest rate. The compen-

*Dartmouth College, Hanover NH 03755 and NBER, Cambridge, MA 02138; and Texas Tech University, Lubbock, TX 79409, respectively. We are grateful for data provided by Katherine H. Hanson of the Consortium On Financing Higher Education, to Euysung Kim, Scott Miller and Fony Suryapranata for research assistance, the Department of Education for research support, and Steven Venti, Olivia Mitchell and W. Lee Hansen for comments. This paper is part of the NBER programs in Labor Studies and Aging. Any opinions expressed are solely our own.

sation function reflects the effects of wages, pensions, and Social Security, with the effects of pensions and Social Security calculated as the difference in the present value of benefits attributable to additional work.

The data used in the structural retirement analysis pertain to arts and sciences faculty employed by these schools on December 31, 1978, to retirees from these schools from the 1973–74 academic year through the end of 1978, and to the pensions and retirement programs reported by these schools in August 1979. For each faculty member employed over the covered period, the following information is provided in the survey: date of birth; sex; date of entry into tenured track status; indicators of tenure status; date of tenure; 9-month salary rate; full or part-time status; date of retirement, departure or termination, if appropriate; whether, in the case of a departure, it was due to mandatory retirement; and other information about the faculty member.

Importantly, however, no information is available on health status. Each school is identified. For the 1979 period, pension plan provisions, early retirement and flexible retirement policies are reported for each school in separate COFHE documents. (These data have also been used by John Blackburn and Susan Schiffman, 1980; and J. Russell Southworth and Ronald Jagmin, 1979.) For later simulations, we have obtained descriptions of these plans for 1989 directly from the schools.

In constructing the opportunity set, wage equations for full and part-time work are estimated. (These equations are in a statistical appendix available upon request.) Wages are projected using the experience and tenure coefficients from the wage equations, assuming a general wage growth equal to the growth of average hourly earnings nationally. Social Security benefits are calculated on the basis of the rules that were applicable to each cohort (see our 1985 article). The calculations include retired worker benefits, spouse benefits, and survivor benefits. Required faculty pension contributions are subtracted from wages.

In 1979, normal retirement (NR) age was 65 in 18 of the COFHE schools in the

sample, 66 in 1, 68 in 5, and 70 in 2. From 1979 to 1989, the median normal retirement age remained at 65, but 5 schools reduced the normal retirement age from 70 or 68 to 65. Mandatory retirement (MR) age was 65 in 5 schools, 68 in 5 schools, 70 in 9 schools, and 7 did not report a mandatory retirement age. By 1989, mandatory retirement age was 70 at all 26 schools. Separate information is also provided on the actual application of mandatory retirement to each of the cases in the sample (Southworth-Jagmin). The fractions of retirements in the sample which were mandatory are 78, 99, and 97 percent for those 65 to 67, 68 to 69, and 70 to 72 years-old, respectively.

At 7 schools, early retirement (ER) supplements were generally available in 1979, and at 4 schools they were available on an *ad hoc* basis. The availability of these programs has spread rapidly over time. For the 1979 sample of 26 schools, at the plan's early retirement age, pension wealth amounts to 5.9 times earnings. At normal retirement age, the wealth-yearly earnings ratio rises to 6.0 to 1, and at mandatory retirement age, pension wealth averages 6.8 times yearly earnings. By 1989, formal early retirement programs were available at 23 of 29 schools reporting to COFHE, with *ad hoc* programs at the other 6.

Table 1 highlights the accrual of pensions and any early retirement bonuses. In calculating the accrual profiles, the table uses the average birth date and wage profiles by institution and then weights the results by the number of tenured faculty at each institution. It can be seen from Table 1 that even though we are dealing with defined contribution plans, early retirement programs available at the schools create significant spikes in the accrual profile.

The preretirement period (PR) is the 5 years preceding the year before eligibility for early retirement benefits. The ER spike is computed over the year in which eligibility for early retirement benefits is obtained, and the NR spike is computed over the year before eligibility for normal retirement benefits is obtained. Early Retirement (ER) is the period between the periods for computing the ER spike and NR spike. Finally, Late Retirement (LR) is the period be-

TABLE 1—INCREMENT IN PENSION WEALTH AND
EARLY RETIREMENT BONUS/EARNINGS

Age at Hire	PR	ER Spike	ER	NR Spike	LR
Early Retirement Available					
25	15.4%	149.6%	-19.5%	-10.1%	0.1%
35	15.4	154.3	-19.9	-10.8	0.1
45	15.2	80.2	0.4	1.6	0.5
No Early Retirement Available					
25	14.1%			21.1%	8.2%
35	14.1			21.1	8.2
45	14.1			34.5	8.2

Note: PR: preretirement period; ER: early retirement; NR: normal retirement; LR: late retirement.

tween attaining eligibility for normal retirement benefits and mandatory retirement.

The sharp increments in the accrual rates reflect the attainment of eligibility for early or normal retirement benefits, where eligibility is accompanied by a bonus. In one plan, for example, those retiring early receive 60 percent of yearly salary between ages 62 and 65. On average, covered individuals hired at age 35 become eligible for a supplement worth 1.5 years of salary when they reach the early retirement age.

The survey also provides information on whether the individual was working part time at the end of the survey or at the date of retirement, if earlier. If more than 10 percent of retirements from a school are from part-time work, partial retirement is assumed to be generally available at the school.¹

Consider now the structure of the dependent retirement variable. For many of those in the sample, it is possible to determine a sequence of outcomes for 6 years. For those who have retired, there is information on status just before retirement. However, the sample of retirees from COFHE schools is not a true panel. For those who were partially retired as of December 31, 1978, the duration of partial retirement is not reported. Information is not provided indicating who partially retired after having left a state in which they worked full time and

TABLE 2—PARAMETER ESTIMATES

whose lifetime job at the university involved part-time work. In an effort to distinguish partial retirees who reduced work effort from full time from those who were only part-time employees during prime working age, the sample includes only tenured faculty. An examination of the frequencies of retirement and partial retirement between the ages 40 and 60, indicates that early leaving and part-time work by tenured faculty are not important in the sample. (The frequency distribution of retirement sequences for the 6 years covered by the survey are reported in an Appendix and in a report to the Department of Education, both available on request.)

II. Empirical Findings

Parameter estimates from the model are presented in Table 2, with asymptotic standard errors indicated in parentheses below each figure. γ and ρ are parameters of the distribution of δ and ϵ . The data were fit to males in cohorts born from 1909 through 1912. The estimation procedure follows our article (1986a), with one modification. Those who retired before 1974 were not included in the sample. Accordingly, the estimation procedure attempts to correct for selection due to prior retirements using early retirees from younger cohorts, a correction that was not required in our earlier work. The parameters are significant at standard levels.²

¹Although our estimates assume that partial retirement involves a reduction in official hours at work, it is also possible that minimum hours constraints may be less binding in academia than elsewhere.

²There were 5 observations in which individuals retired the year before becoming eligible for early retirement bonuses worth an additional 1 or 2 year's

TABLE 3—ACTUAL AND SIMULATED
EMPLOYMENT PERCENTAGES

Age	Actual		Simulated	
	FT	PT	FT	PT
62-64	87.6%	3.9%	76.6%	5.9%
65-67	38.9	15.0	38.6	7.1
68-69	12.7	12.7	17.2	6.2
70-72	1.6	5.6	6.2	4.0

Note: FT: full-time work, PT: part-time work.

COFHE faculty retired later than did workers covered by the Retirement History Survey. By age 64, 39 percent of healthy males in the survey without a pension had left full-time work, while only 14 percent of all faculty in the COFHE sample had. These differences are reflected in differences in the estimated constant, but the coefficients estimated for the effects of aging are similar for the two samples. This suggests that although, for any given opportunity set, the levels of retirements are higher in the COFHE sample, the changes in retirement rates induced by a given incentive will be similar.

Simulation is accomplished by applying Monte Carlo techniques. For each observation, five random draws are taken for the stochastic terms δ and ε in the utility function. Table 3 simulates the percentages working full and part-time by age using the pensions and Social Security rules in place during the sample period. The percentages resulting from a simple nonparametric hazard model are presented for comparison. The model simulates the substantial drop in work effort during the period fairly well, although it has some trouble capturing the large increase in part-time work after age 65.

salary. In a model such as the one used in this paper, such an event would occur only if the coefficient on age in the utility function were implausibly high, implying almost no response of retirement behavior to economic incentives. Since these 5 retirements may well be due to health problems that, in the absence of information on health status, cannot be controlled for, and since these observations would dominate the results if they were included, these 5 observations are excluded from the sample.

TABLE 4—EFFECTS OF RAISING MANDATORY
RETIREMENT AGE

Age	Percentages Working Full Time with 1979 Pensions		
	Actual MR	MR = 70	No MR
65-67	38.6%	65.6%	64.7%
68-69	17.2	53.8	53.0
70-72	6.2	6.2	43.4

Note: MR: mandatory retirement.

Table 4 presents the results of simulations that raise the mandatory retirement age, holding other aspects of the compensation profile the same. The first column uses the actual mandatory retirement ages observed in the sample, while the following two columns raise the minimum mandatory retirement age to 70 and eliminate it, respectively. Reflecting the frequency with which individuals worked until mandatory retirement, these simulations suggest massive increases in full time work by faculty members in their late 60s and early 70s. As a word of caution, the simulations in column 3 take us outside the age range of observation for those in the sample. For that reason, and because we do not have information on health status, those results should be interpreted with some care.

Using the observed 1989 pension plans, all of which specified age 70 as the mandatory retirement age, we also simulated the effects of early retirement supplements. Compared to a situation where the early retirement supplements are suppressed, the observed supplements for each school reduce the percent working full time from 66.7 to 65.9 percent for 65 to 67 year-olds, and from 55.1 to 53.7 percent for 68 to 69 year-olds. Therefore, if the early retirement provisions in the pensions available in 1989 were abolished, there would be little overall effect on observed early retirement behavior.

We also simulated the effects of uniformly adopting one school's 1989 early retirement plan, a plan that provides up to 40 percent (1.33 percent per year of service) of salary either up to 5 years or until age 70, whichever is sooner. For this plan we find that full-time work is reduced to 64.4 per-

cent for 65 to 67 year-olds, and to 51.0 percent for 68 to 69 year-olds, a relatively small effect. Thus early retirement incentive plans do not appear to be very effective, at least in the COFHE schools.

When the costs of the retirement plan are simulated, three elements are of importance: the rent paid to those who would have retired at younger ages on the basis of unchanging retirement behavior; the reduction in costs due to accelerated retirement by some highly paid faculty; and the costs of replacement faculty. Our calculations (shown in the Appendix) indicate that rents exceed the savings due to early retirement, so that even ignoring the costs of replacement faculty, this type of early retirement incentive plan will not be cost saving.

III. Conclusions

The data used in this study are old, are not strictly longitudinal, are missing key pieces of information on health status, family structure, field of specialization, and postretirement behavior outside the primary employer, and apply only to a limited and not representative sample of colleges and universities. These limitations mean that the findings from this study should be applied with caution. Nevertheless, the preceding analysis indicates the feasibility of adapting recent innovations in the retirement literature for analysis of retirement policies by institutions of higher education.

Simulations suggest that for the COFHE schools, extending and then eliminating mandatory retirement will lead to a significant number of faculty to postpone retirement.

Some institutions of higher education are considering early retirement incentive programs that will have costs and benefits that are very sensitive to the induced retirement responses. For these plans to be cost saving, the savings from inducing earlier retirement by higher-paid senior faculty must exceed the costs from rents accumulating on the basis of unchanging retirement behavior and replacement costs. Our calculations suggest they will not. An obvious alternative option that might be considered in an effort to

influence faculty retirement is the adoption of a defined-benefit plan, that is offered at many public institutions of higher education, and that can create even stronger early retirement incentives.

The effects of retirement incentives created by innovative retirement programs, the associated program costs, and implications of related policy initiatives, may all be analyzed with analytical tools that are currently available. All that is required is the availability of the required data.

Conflict and Attitudes Toward Risk

By STERGIOS SKAPERDAS*

The outcome of conflict is rarely known with certainty before it occurs. This is true even when those involved have perfect information about each other's capabilities and idiosyncracies. In military contexts there is enough residual uncertainty in the battlefield so that the side with the superior force cannot be guaranteed to win. Similarly, in cases of economic warfare (trade wars, battles for market share, rent-seeking situations), greater expenditure of resources than one's opponent does not necessarily yield a higher *ex post* payoff. Consequently, one would expect attitudes toward risk to influence the strategic choices made by parties that are about to engage in conflict and, through these choices, the likelihood of winning.

This paper explores the effect of differential attitudes toward risk in a model of conflict.¹ Is greater risk aversion than one's opponent advantageous or not, and does increasing risk aversion reduce or increase the resources expended on conflict? These are the two main questions examined under two alternative institutional arrangements.

I. When Conflict is Inevitable

The model employed here is a variation on models analyzed by Jack Hirshleifer

[†]*Discussants:* Michelle R. Garfinkel, Federal Reserve Bank of St. Louis; Martin C. McGuire, University of Maryland.

*Department of Economics, University of California, Irvine, CA 92717. I am grateful to Chew Soo Hong, Ami Glazer, Jack Hirshleifer, Dan Klein, and Klaus Nehring for helpful comments.

¹The role of risk in conflict is a recurring theme in Thomas Schelling's work (1966, see ch. 3). In other related work, John Gould (1973) has explored the role of risk aversion in producing out-of-court settlements in legal conflicts.

(1988) and by myself (1990). There are two parties, labeled 1 and 2, each possessing one unit of an initial resource. The decision facing each party is how much of the resource to convert into arms, leaving the remainder for useful production. Letting y_i denote the quantity of arms chosen by party i ($= 1, 2$), $1 - y_i$ represents the party's remaining productive resource. The relative quantity of arms determines the probability of each party to win in conflict. The winner receives a prize that depends on the remaining productive resources of both parties. The prize is a function $C(1 - y_1, 1 - y_2)$ which is increasing in both arguments; the loser receives nothing. Let $p(y_1, y_2)$ be a function (increasing in y_1 and decreasing in y_2) that represents the win probability of party 1, while $1 - p(y_1, y_2)$ represents the win probability of party 2. In addition, for a given (y_1, y_2) pair we have $1 - p(y_1, y_2) = p(y_2, y_1)$ so that having equal win probabilities is equivalent to $y_1 = y_2$, and a party has higher win probability than her opponent if and only if she has a greater quantity of arms. Both parties are expected utility maximizers and 2 is *strictly more risk averse* than 1 in the Arrow-Pratt sense. Then, with $U(\cdot)$ and $V(\cdot)$ being the $VN - M$ utility functions of 1 and 2, respectively, there exists an increasing and strictly concave function $k(\cdot)$ such that $V(\cdot) = k(U(\cdot))$. Letting $V(0) = U(0) = 0$, the expected payoffs for a given choice of arms allocations, (y_1, y_2) , are

$$(1a) \quad \pi^1 = pU(C)$$

$$(1b) \quad \pi^2 = (1 - p)V(C) = (1 - p)k(U(C))$$

where $p \equiv p(y_1, y_2)$ and $C \equiv C(1 - y_1, 1 - y_2)$. While the prize the winner receives depends on the strategic choices of both

parties and is thus endogenous, the loser's payoff is independent of the strategies adopted. The latter feature is partly responsible for the unambiguous results obtained below.

The first objective is to find out whether the less risk-averse side has a higher or lower win probability in equilibrium than her opponent. In order to isolate the effect of differential attitudes toward risk, I consider a *symmetric* function $C(\cdot, \cdot)$ in the sense that for any z and w , we have $C(z, w) = C(w, z)$, implying that $C_1(z, w) = C_2(w, z)$ where the subscript 1 (2) denotes the partial derivative with respect to the first (second) argument of $C(\cdot, \cdot)$. (Otherwise, $C(\cdot, \cdot)$ has the properties of non-increasing marginal products and a non-negative cross derivative; within these constraints, returns to scale can be increasing, constant, or decreasing.) The two parties choose their strategies, y_1 for 1 and y_2 for 2, simultaneously. Attention is restricted to interior Nash equilibria where both sides choose a positive quantity of arms. Then, by differentiating (1a) with respect to y_1 and (1b) with respect to y_2 , and by setting the derivative equal to zero, at any equilibrium point, we have

$$(2a) \quad p_1 U(C) = p U'(C) C_1$$

$$(2b) \quad -p_2 k(U(C)) \\ = (1-p) k'(U(C)) U'(C) C_2$$

where the subscripts 1 and 2 denote partial derivatives with respect to the first and second arguments of the relevant function (no special notation is used here for the equilibrium values of the relevant functions and variables). The left-hand side of each equation represents the marginal benefit (the change in the win probability times the utility of the prize) associated with a small increase in a party's quantity of arms, while the right-hand side represents its marginal cost. Dividing (2a) by (2b) and rearranging yields

$$(3) \quad (C_1/C_2) k(U(C)) \\ = k'(U(C)) U(C) \frac{p_1(1-p)}{-p_2 p}.$$

The strict concavity of $k(\cdot)$ along with the normalization $k(U(0)) = U(0) = 0$ implies that for any $C > 0$ we have

$$(4) \quad k(U(C)) > k'(U(C)) U(C)$$

and its application in (3) yields

$$(5) \quad C_1/C_2 < p_1(1-p)/(-p_2 p).$$

Suppose, for a moment, that the less risk-averse party (1) has a higher win probability in equilibrium so that $p > 1/2$ and $y_1 > y_2$. Since $1 - y_1 < 1 - y_2$, it follows that $C_1 \equiv C_1(1 - y_1, 1 - y_2) \geq C_1(1 - y_2, 1 - y_1)$. The symmetry of the production function also implies that $C_1(1 - y_2, 1 - y_1) = C_2(1 - y_1, 1 - y_2) \equiv C_2$ which, by the last inequality, yields $C_1 \geq C_2$. Therefore, the right-hand side of (5) is strictly greater than 1. Under a rather weak assumption, however, which also guarantees existence of equilibrium,² it can be shown that the right-hand side of (4) is greater than one if and only if $p < 1/2$. Hence, the initial supposition of $p > 1/2$ is contradicted and we must have $p < 1/2$ at any interior equilibrium. In conclusion, the more risk-averse party always has a higher win probability in equilibrium and thus being *more risk averse than one's opponent is advantageous when conflict is inevitable*.³ The quantity of arms invested by each party can be thought of as insurance against losing in conflict. Since the more risk-averse party can also be thought of as more fearful of losing, that party will also invest more in arms and thereby have a higher win proba-

²The assumption is that $p_{11}p < p_1^2$ and, equivalently, $-p_{22}(1-p) < p_2^2$ where the subscripts denote derivatives with respect to the first and second arguments of $p \equiv p(y_1, y_2)$. This assumption is satisfied by any p function that is concave in its first argument as well as for others that are not "too convex." The proof of this result and of existence of equilibrium can be found in my earlier paper. It should be noted that existence of equilibrium does not necessarily preclude the two sides from being risk lovers; the production function could compensate for the nonconcavity of the utility functions.

³This result does not depend on having a unique pure-strategy equilibrium. If multiple interior equilibria were to exist, the result would hold for every single one of them.

bility.⁴ The intuition for the second result of this section, to which I now turn, is similar.

To consider the effect of increasing risk aversion on the total amount of resources expended on conflict, two simplifying assumptions are introduced. First, the two parties are now identical in their risk attitudes in addition to the model's other attributes. Thus, we seek to compare a situation where the utility function of both parties is described by $U(\cdot)$ to that where the utility function is $k(U(\cdot))$. Second, there is a unique equilibrium that together with the assumption of identical parties implies that the equilibrium must be symmetric and, therefore, the two sides choose the same quantity of arms and they have equal win probabilities. When the utility function is $U(\cdot)$ (respectively, $k(U(\cdot))$), the reaction function of either party is represented by $r^u(\cdot)$ (respectively, $r^v(\cdot)$) and the equilibrium quantity of arms is denoted by y^u (respectively, y^v). For each $i = u, v$ we have $r^i(y^i) = y^i$ and $r^i(0) > 0$ (otherwise, $(0, 0)$ would be an equilibrium). Then, since y^i is a unique and symmetric equilibrium, it must be the case that $r^i(y) > y$ for all $y \in [0, y^i]$. It can also be shown, using the first-order conditions along with (4), that $r^v(y) > r^u(y)$ for all $y \in (0, 1)$. If we had $y^v \geq y^u$, the two just-derived inequalities would imply that $y^v \leq r^u(y^v) < r^v(y^v)$, which contradicts $r^v(y^v) = y^v$. Hence, we must have $y^v > y^u$ and, therefore, *as the two sides become more risk averse, the amount of resources expended on conflict increases.*

II. When Settlement is Possible

Up to this point it has been assumed that open conflict is inevitable, but this need not

be the necessary outcome of interaction between the two parties even after both have armed themselves. Any simultaneous choice of arms determines each side's win probability and the size of the prize, C , that the winner receives. Now suppose that the two parties can communicate and are able to divide the prize in any way they agree. An agreement can be defined as a number β (between 0 and 1) where β represents the share of the prize received by party 1 with the remainder, $1 - \beta$, going to party 2. Then, the payoffs under some agreement β would be as follows (where the utility functions are as in (1)):

$$(6a) \quad \pi^1(\beta) = U(\beta C)$$

$$(6b) \quad \pi^2(\beta) = V((1 - \beta)C) \\ = k[U((1 - \beta)C)].$$

For an agreement to be credible, it would be necessary for both parties to be at least as well off as under open conflict. Otherwise, the party with lower payoff under the agreement could declare war. Formally, an agreement β is *credible* if and only if $\pi^i(\beta) \geq \pi^i$ for both $i = 1, 2$ where π^i is as defined in (1). If both parties were risk averse, it can be shown easily that the range of credible agreements would be an interval $[\beta, \bar{\beta}]$ such that $U(\beta C) = pU(C)$ and $k[U((1 - \bar{\beta})C)] = (1 - p)k(U(C))$. Note that this range of agreements depends on p and C , with both determined by the simultaneous strategic choices of the two parties, and on the utility functions. Since with risk aversion we have $U(pC) > pU(C)$ and $k[U((1 - p)C)] > (1 - p)k(U(C))$, the division of the prize according to the win probabilities belongs to the set of credible agreements.

With both parties being risk lovers, however, the set of credible agreements is empty; the two inequalities stated above are reversed and β is always strictly less than $\bar{\beta}$. In this case conflict would always take place. When one party is risk averse and the other one is a risk lover, credible agreements may not exist depending on the specific utility functions and the other parameters of the model.

⁴Alternatively, it could be argued that the more risk-averse party would be less willing to "gamble" on winning the conflict and thus be at a disadvantage. This intuition, which is completely opposed to the one materialized in my model, is not totally misplaced and it leads to ambiguous effects in the single-agent analog to the problem explored here, the problem of self-protection (see Georges Dionne and Louis Eeckhoudt, 1985, and Martin McGuire et al., 1991). As mentioned earlier, the unambiguous result obtained here is partly due to the fact that the loser's payoff is independent of the amount of arms investment.

For the remainder of this section it is assumed that both parties are risk averse, leaving a nonempty set of credible agreements. For any given choice of arms (y_1, y_2) , the two parties face a bargaining problem with the payoffs in (1) representing the disagreement payoffs and a payoff (or, utility) possibilities set whose frontier can be derived from (6). In terms of shares of the prize C , an agreement could be reached anywhere in the interval of credible agreements $[\beta, \beta]$. Without a determinant bargaining outcome, a rule assigning to each (y_1, y_2) pair a unique β , no results about the effect of risk attitudes are forthcoming. But suppose for the moment that the outcome of bargaining is such that the prize is always divided according to the win probabilities with parties 1 and 2 receiving pC and $(1-p)C$, respectively. Then, the payoff functions in (6) would be $\pi^1(p)$ and $\pi^2(p)$. Note that p and C are functions of (y_1, y_2) , and although conflict will not occur, each side invests in arms so as to balance the marginal benefit of a better bargaining position against the marginal cost associated with the reduction in the value of the prize. At an interior equilibrium point, the following first-order condition must be satisfied for 1:

$$(7) \quad U'(pC)[p_1C - pC_1] = 0$$

implying that $p_1C - pC_1 = 0$, which does not depend on the utility function. Instead, party 1 (and by a similar argument, party 2) behaves as if he were risk neutral. In addition, it can be shown that in this case the two sides of (5) are equal and that the prize would be split in half. Thus, *in this special case about the outcome of negotiations, attitudes toward risk do not have any influence on the strategic choices of the two parties.* Furthermore, since identical risk-averse parties would expend greater resources under conflict than identical risk-neutral parties would, and the two parties under the settlement arrangement behave as if they were risk neutral, fewer resources are wasted when settlement is possible than when it is not.

Although setting the bargaining agreement equal to p is the simplest possible rule

the two parties could follow as it is a natural "focal point," it has drawbacks. If party 1 were risk neutral and party 2 were risk averse, we would have $p = \beta$ which is the worst possible agreement for party 1. This example suggests a bias of this rule in favor of the more risk-averse party and is indicative of the possible inconsistencies one might discover in other examples. An alternative approach would be to employ an axiomatic bargaining solution, like the Nash or the Kalai-Smorodinsky solutions (Alvin Roth, 1979, contains a comprehensive analysis of this topic) that satisfy a set of properties (axioms) and are thereby consistent across different situations. Both of these solutions have been shown to favor the least risk-averse side (see Roth) when the disagreement point and the bargaining possibilities are deterministic, but the effect of employing either solution in the model of this paper is an open question.

III. Conflict or Settlement?

If at least one party is a risk lover, the set of credible agreements may be empty, implying conflict. The absence of the necessary communication channels for facilitating settlement is a second reason for entering into conflict. In turn, lack of communication could be due either to exogenous factors outside the control of the two parties, or to a prior strategic move by just one party. Obviously, after armament levels have been chosen, and in the presence of credible agreements, the incentive not to communicate or purposely destroy the channels of communication would not exist. Only in the case where one party would be better off if there were no possibility of communication (i.e., the payoff for that party would be higher under the institutional arrangement in Section I than that in Section II) would there be an incentive to make in advance an irrevocable commitment not to communicate when the time, and the temptation, to do so comes. This commitment must take the form of a "burn-the-bridges" act for the opponent to be convinced of its irrevocability.

What are the conditions that would make such a commitment profitable, or, in other

words, when would one side prefer the institutional arrangement of Section I? An answer to this question would depend on the particular assumptions employed about the outcome of bargaining in Section II. Some insight can be gained by considering the special case where, if the parties were to settle, they would agree on dividing the prize in accordance with the win probabilities. Recall that in this case, both sides would behave as if they were risk neutral which implies, given the symmetry of the model, that the prize would be split in half. In addition, recall from Section I that the less risk-averse party has lower win probability (less than $1/2$) when conflict is inevitable, and since the prize would be smaller as well under this arrangement, it follows that the less risk-averse party would always prefer the arrangements where settlement is possible and thus never commit to conflict. Although the prize would be smaller under conflict, the fact that the more risk-averse party has greater win probability under it implies that the settlement arrangement would not be necessarily preferable and, thus, if commitment to conflict were possible, it could only be optimal for the more risk-averse party.

Note that if the equilibrium under the settlement arrangement were to favor the least risk-averse party, the possibilities for the more risk-averse party instigating conflict by committing to it in advance would increase. Overall, a settlement and bargaining arrangement known to favor one party

runs the risk of driving the other one to conflict. The avoidance of strategic uncertainty about the outcome of negotiations, an important but difficult-to-model issue left out thus far, is another possible reason for either party, especially the more risk-averse one, to commit to conflict.

The East European Revolution of 1989: Is It Surprising that We Were Surprised?

By TIMUR KURAN*

Many aspects of the East European Revolution are controversial, but on one point everyone agrees: it caught the world by surprise. Even local dissidents were stunned by the sudden turn of events.

We will never know how many East Europeans *did* foresee the explosion of 1989. But at each step, accounts painted a picture of nations united in amazement. To my knowledge, only one study addresses the issue systematically. Four months after the breaching of the Berlin Wall, the Allensbach Institute asked a broad sample of East Germans: "A year ago did you expect such a peaceful revolution?" Only 5 percent answered "yes," though 18 percent responded "yes, but not that fast." Fully 76 percent admitted to being totally surprised. These figures are all the more remarkable given the I-knew-it-would-happen fallacy—the human tendency to exaggerate foreknowledge (Baruch Fischhoff and Ruth Beyth, 1975).

Yet in hindsight the revolution appears as inevitable. In each of the six countries the leadership was despised, economic promises remained unfulfilled, and basic freedoms existed only on paper. More importantly, winds of change in the Soviet Union were making Soviet intervention increasingly unlikely. But if the revolution was indeed inevitable, why was it not foreseen? What kept us from noticing signs that now, after the fact, are so plainly visible?

I. Preference Falsification and Revolutionary Bandwagons

Consider a country featuring two camps competing for political power: government and opposition. Members of society, indexed by i , all place themselves publicly in one camp or the other, although a person may privately feel torn between the two camps. I am thus distinguishing between an individual's *private preference* and *public preference*. The former is effectively fixed at any instant, the latter a variable under his or her control. When his two preferences differ the individual is engaged in *preference falsification* (see my 1990a article).

Let S represent the size of the public opposition, expressed as a percentage of the population. Initially it is near 0, implying that the government commands almost unanimous public support. As a mass-supported seizure of political power, a revolution may be treated as an enormous jump in S .

Now take a citizen who wants the government overthrown. The likely impact of his own public preference on the government's fate is negligible, so his private preference plays no direct role in his choice of whether to side publicly with the opposition. His public preference depends on a tradeoff between two payoffs, one external and the other internal.

The external payoff to siding with the opposition varies positively with S . The larger S , the smaller the individual opponent's risk of being persecuted for his outspokenness, and the fewer hostile supporters of the government he has to face. The latter feature reflects the fact that government supporters, even those privately sympathetic to the opposition, participate in the persecution of dissidents, as part of their personal efforts to establish convincing pro-government credentials.

*Associate Professor of Economics, University of Southern California, Los Angeles, CA 90089-0253. I am grateful to the National Science Foundation for support. Most of my research was conducted during a sabbatical, financed partly by the National Endowment for the Humanities, at the Institute for Advanced Study in Princeton.

The internal payoff is rooted in the psychological cost of preference falsification: the suppression of one's wants generates lasting discomfort, the more so the greater the lie. Specifically, person i 's internal payoff to supporting the opposition varies positively with his private preference, x^i . The higher x^i , the costlier he finds it to suppress his antigovernment feelings. An individual's private preference thus plays an indirect role in his choice of a public preference; as a determinant of his internal payoff to supporting the opposition.

Thus i 's public preference depends on S and x^i . As S grows, with x^i constant, there comes a point where the external cost of joining the opposition is outweighed by the internal cost of self-suppression. This switching point is i 's *revolutionary threshold*, T^i . Note that if x^i should rise, T^i will fall.

People with different private preferences and psychological constitutions may differ in their revolutionary thresholds. Imagine a ten-person society featuring the *threshold sequence* $A = \{0, 20, 20, 30, 40, 50, 60, 70, 80, 100\}$. Person 1 ($T^1 = 0$) supports the opposition regardless of its size, just as person 10 ($T^{10} = 100$) always supports the government. The remaining eight people's public preferences are sensitive to S . Initially, the opposition consists of a single person, or 10 percent of the population, so $S = 10$. Because the nine others have thresholds above 10, this S is self-sustaining.

This equilibrium happens to be vulnerable to a minor change in A . Suppose that person 2 has an unpleasant experience with the government, which exacerbates her alienation from the regime. The consequent rise in x^2 lowers T^2 from 20 to 10. Since $S = 10$, person 2 joins the opposition, moving S to 20. This new S is self-augmenting, as it drives person 3 into the opposition. The S of 30 then triggers a fourth defection, and in this manner S feeds on itself until it reaches 90—a new equilibrium. A slight shift in one individual's threshold has thus generated a *revolutionary bandwagon*, an explosive growth in public opposition.

Now consider the sequence $B = \{0, 20, 30, 30, 40, 50, 60, 70, 80, 100\}$, which

differs from A only in its third element: 30 as opposed to 20. As in the previous illustration, let T^2 fall from 20 to 10. Once again, the preexisting equilibrium becomes unsustainable, and S rises to 20. But the opposition's growth stops there, for the new S is self-sustaining. We see that a minor variation in thresholds may alter drastically the effect of a given perturbation.

Neither private preferences nor the corresponding thresholds are common knowledge. So a society can come to the brink of revolution without anyone knowing this—not even those with the power to unleash it, like person 2 in A .

For any number of reasons the threshold sequence may shift dramatically in favor of the opposition. But this will not necessarily trigger a revolution. In the sequence $C = \{0, 20, 20, 20, 20, 20, 20, 20, 60, 100\}$, the average threshold is as low as 30, possibly because in private most people sympathize with the opposition. Yet $S = 10$ remains an equilibrium.

When a revolutionary bandwagon does take off, long-repressed grievances burst to the surface. In addition, people who were relatively content embrace the new regime, attributing their former public preferences to fear of persecution. Reconsider A , recalling that a 10-unit fall in T^2 drives S from 10 to 90. The last person to jump on the bandwagon has a threshold of $T^9 = 80$, a reflection of her great sympathy for the government. Accordingly, she does not switch until the opposition's victory is guaranteed. Having made the switch, she has every reason to feign a longstanding antipathy to the old regime. In doing so, she makes it seem as though the old regime enjoyed even less genuine support than it actually did. This illusion is rooted in the very factor responsible for making the revolution a surprise: preference falsification. Its effect is to make it even less comprehensible why the revolution was unforeseen.

The outlined theory (for details, see my 1989, 1990b papers) unites social evolution and revolution, continuous and discontinuous change, in a single model. Private political preferences and the corresponding thresholds may shift gradually over a long

period during which public opposition is stable. When the cumulative change has established a *latent bandwagon*, a minor event may precipitate a sharp jump in public opposition.

II. The Revolution of 1989

Given communism's failures, the existence of East European dissent is easily understood. Less comprehensible is the rarity of dissent—prior, that is, to 1989. For decades, East Europeans displayed a remarkable capacity to put up with tyranny and inefficiency.

This subservience is attributable partly to punishments the communist establishment imposed on nonconformists. Yet official repression is only one factor in the durability of communism. It met with the approval of disillusioned citizens and relied crucially on their complicity. People with every reason to despise the status quo applauded politicians they mistrusted, joined organizations whose mission they opposed, and signed defamatory letters against dissidents they admired, among other manifestations of consent and accommodation.

In a famous essay, Václav Havel (1979) speaks of a greengrocer who places in his window the slogan "Workers of the World, Unite!" Why does he do this, Havel wonders, "Is he genuinely enthusiastic about the idea of unity among the workers of the world? Is his enthusiasm so great that he feels an irrepressible impulse to acquaint the public with his ideals? Has he really given more than a moment's thought to how such a unification might occur and what it would mean?" (p. 27). No, the greengrocer does not mean to express his real opinion about anything. He displays the slogan simply for the right to be left alone.

The greengrocer's prudence has an unintended consequence: it reinforces the perception of a society united behind the Party. It thus becomes a factor in other people's willingness to continue doing and saying the things expected of *them*.

Later in the same essay, "something in our greengrocer snaps" and he makes "an attempt to *live within the truth*" (p. 39). As a

consequence, he is transferred to the warehouse at reduced pay, and his hopes for a holiday in Bulgaria evaporate. Also, his peers take to harassing him—not out of inner conviction but to avoid being persecuted themselves.

This brilliant vignette suggests that the regimes of Eastern Europe were substantially more vulnerable than the quiescence of their populations made them seem. Millions were prepared to turn against communist rule if ever this became safe to do.

What lowered the level of fear sufficiently to get the revolution underway? With the benefit of hindsight it appears that Gorbachev's reforms in the Soviet Union played a key role. In Eastern Europe these kindled hopes of greater independence and meaningful social change. But why did we not foresee where they would lead?

An examination of the news media before the revolution shows that arguments in the air pointed to the unlikelihood of fundamental change. Even if Gorbachev wanted to liberate Eastern Europe, it was not clear that he could. Surely, Soviet conservatives would insist on retaining their country's security belt. Moreover, tensions within the Soviet Union were sowing the seeds of a conservative coup. Some observers expected Gorbachev to survive, but only by reversing course and becoming increasingly repressive.

For all this pessimism, Gorbachev's policies did fuel expectations of a freer Eastern Europe, reducing the perceived risk of dissent. In terms of our model, they shifted the thresholds of East Europeans increasingly in favor of revolt, making it ever easier to spark an explosion. But obvious as this was, no one could see that public sentiment would shift so soon and so massively.

Pinpointing the specific event that pushed the bandwagon over the hill is akin to identifying the cough responsible for a flu epidemic. There were several turning points, any one of which might have altered history. One came when East German officials cancelled Party leader Honecker's order to fire on demonstrators in Leipzig. The demonstration's peacefulness made many more East Germans sense that change was im-

minent. Another turning point came with Gorbachev's remark that his country had no right to interfere in the affairs of its neighbors. At the time, some East European leaders were contemplating the use of force, and this statement may well have been a major factor in their exercising restraint.

When the greengrocers decide that they have had enough, Havel had predicted, East European communism will collapse like a house of cards. So it turned out: when the masses took to the street, support for the status quo just vanished. In one country after another a few thousand people stood up in defiance, joining long-persecuted activists. In so doing they encouraged additional citizens to drop their masks, which then impelled more onlookers to jump in. Before long, fear changed sides: where people had been afraid to oppose the regime, they came to fear being caught defending it. Party members rushed to burn their cards, claiming they were always reformists at heart. Top officials began sensing that they might face retribution for resistance. They hastened to accept the opposition's demands, only to be confronted with bolder ones (for a chronicle of events, see Timothy Garton Ash, 1990).

The East European Revolution has been billed as the triumph of truth over lying. This designation conveys the end of feigned support for communism, but it conceals the continuation of preference falsification. Lying has not ceased but changed character. Now it provides cover to East Europeans afraid to admit their yearnings for the old order.

III. Is It Surprising that We Were Surprised?

It is tempting to attribute our amazement at the events of 1989 to the inadequacy of our theories concerning political stability. Our most popular theories of revolution certainly left us ill-prepared for the suddenness with which public sentiment turned. For instance, Theda Skocpol's (1979) "structuralist" theory, which shows how changes in international relations can produce social uprisings, does not explain the involved discontinuities. A solid under-

standing of the interdependencies among individual public preferences (whose significance Skocpol explicitly rejects) would doubtless have prepared us better for an East European explosion.

Yet, once again, these interdependencies are largely hidden from view. And for reasons explained above, the knowledge that preference falsification is pervasive does not suffice to establish that a revolution is imminent. We can sense that multitudes are seething with unarticulated discontent without knowing what it would take to turn the possibility of revolt into reality. In principle, of course, we can develop techniques for uncovering the relevant interdependencies. But for all practical purposes we lack the means to find and process all the requisite information. Also, there are irremovable political obstacles to the correct interpretation of whatever information is produced. In view of all this, it is safe to say that no theorizing could have prepared us adequately for 1989.

I ought to point out that this is not the first time a major uprising has come as a surprise. The French Revolution of 1789, the Russian Revolution of February 1917, and the Iranian Revolution of 1979-80 are among the successful revolutions that stunned their leaders, participants, victims, and observers. The failed ones include the Hungarian uprising of 1956 and the Prague Spring of 1968. In all these cases, preference falsification was a prime factor in the suddenness with which public sentiment shifted—and in the cases of failure, shifted back.

Because preference falsification afflicts politics in every society, though in varying forms and degrees, we are likely to be surprised again and again. But obstacles to predicting particular revolutions do not rule out the production of useful general insights into the *process* of revolution. Even if we cannot predict the time and place of the next big uprising, we can prepare ourselves mentally for the mass mobilization that will bring it about. Equally important, we can understand why it may surprise us. There are many spheres of knowledge where useful general theories foreclose reliable

predictions of specific outcomes. The Darwinian theory of biological evolution illuminates the process whereby species evolve, but without enabling us to specify the future evolution of the swordfish.

The theory of biological evolution and the present argument have a common virtue: each reveals the source of its predictive limitations. In the case at hand, the source is *imperfectly observable nonlinearity*. In ways that we cannot hope to grasp fully, public preferences depend on their determinants nonlinearly. This is why an intrinsically insignificant event may generate a massive rise in public dissent.

The notion that small events may unleash huge forces goes against much of twentieth-century social thought, with its emphasis on linearity and thus continuity and gradualism. So does my suggestion of inescapable unpredictability. Lest this be considered offensive to the scientific spirit, I should note that establishing the limits of knowledge is itself a contribution to the pool of useful knowledge. As Friedrich von Hayek (1974) reminds us, it is also necessary for charting a realistic scientific agenda.

Nations and States: Mergers and Acquisitions; Dissolutions and Divorce

By DONALD WITTMAN*

Many of the most important events in history are associated with the consolidation or dissolution of nations. Alexander the Great founded an empire in a very short time, but its breakup was even quicker. The decline and fall of the Roman Empire has served as a symbol of the temporality of nations. In the more recent past, Hong Kong, Biafra, Eritria, and Northern Ireland are names commonly associated with issues of sovereignty. Within the past year, newspaper headlines have been devoted to the mergers and dissolutions of nations. "Iraq annexes Kuwait," "East and West Germany unite," "Quebec demands greater sovereignty," "Solvenia declares independence" and "The European Economic Community institutes legal reforms" are a small subset of recent examples.

In this article, I provide insight into these historical events by developing an analytic framework for understanding the unification and dissolution of nation states. The basic insight is that wealth maximization (broadly defined) is the underlying fundamental determining the size of nations. I briefly outline some of the efficiency explanations for the size of the polity, then provide a detailed historical example.

I. Efficiency Explanations

As my title suggests, much of our insight regarding states comes from the analogous situation regarding firms and marriages. Firms acquire other firms if the value of the joint firm is greater than the total value of the firms as separate entities. Assets are divested when the assets are of greater value

in the hands of others. Countries should merge when the economic value is greater for a unified country than as separate sovereign states. In theory, economic value is unequivocal if those who want union can bribe those who do not want union, but those who do not want union cannot bribe those who want union to change their minds.¹

Economies of scale and scope are two basic explanations for the size of nations. The costs of administration and policy coordination are unlikely to be proportional to the size of the polity. In warfare especially, there are often great gains in military strength when two small states merge. Firms may create cartels to lessen competition among themselves thereby gaining an advantage on either their suppliers or demanders. In a similar way, countries may create alliances or even merge in order to reduce competition among themselves and gain an advantage over others not in the alliance. At some point, diseconomies of scale arise. The existence of many nations suggests that economies of scale and scope are exhausted before unitary political control of the world is reached.

Different political systems have different economies of scale. Participatory democracy puts severe constraints on the size of the polity. In communist systems, the political apparatus is intricately intertwined with the economic sector. Other things being equal, the optimal size of communist nations is likely to be larger than for capitalist nations since the political scope of the former is so

*University of California, Santa Cruz, CA 95064. I thank the discussant, Martin McGuire, and my colleagues at UCSC for their helpful comments. This article is excerpted from a more extensive working paper with the same title.

¹This model differs from the seminal work of David Friedman (1977) who views each nation as Leviathan. For example, in this model, the shape of the country allows for minimal migration and hence maximal taxation of labor. His model does not consider the desire by the populace to minimize the ability of a country to undertake such extortion.

much more extensive.² An international regime of free trade among nations allows for smaller-scale political units since economic production is not limited to domestic markets. Administrative technology also plays a role. Préliterate societies tend to be less extensive than those that can keep records.

Synergy arises when the merger of the two unique nations produces more than the sum of the parts. Synergy is maximized when the set of merged states creates greater wealth than any other combination of states. It seems plausible that the combined energies of Madison, Hamilton, and Jay in creating *The Federalist Papers* and the ensuing federation was greater than if each had spent his energies in developing his own separate state (Virginia, New York, and New York). Africa is the great natural experiment where one can observe the various combinations of colonial powers with indigenous tribes and their residual effect on the polity after independence was achieved. At one time, Lebanon was an example of synergy. The combination of Christian and Moslem populations created a cosmopolitan country, attracting tourists from the stricter neighboring Moslem countries and serving as a financial center for the Mideast.³ Negative synergy arises when the combination creates disfunction.

In the economic sector, sometimes the best way for a firm to gain access to the *unique* skills associated with another firm is to become part of the more successful firm. Thus one firm may take over another because the firm's CEO and administrative apparatus will create more wealth for the targeted firm than its existing administration.

Similar phenomena occur within the political sector. Consider the recent unifica-

tion of Germany. The economic advantages to East Germany of uniting with West Germany are quite obvious. There are also great political advantages. Rather than creating a democratic society out of whole cloth, the East Germans gained liberal democratic and relatively noncorrupt institutions at low cost by becoming part of united Germany.⁴ A closer analogy to a stock takeover is the secession of Charles II of Spain in 1700. England, France, and the United Provinces were scheming to divide Spain. Rather than accept such a division, the king offered all of his realm as an indivisible bequest to the strongest of the claimants, France, but only if the integrity of the country and monarchy remained; if Phillip, the grandson of Louis XIV, refused to abide by this, then the crown would be bequeathed to Archduke Charles of Austria on the same terms. The installation of Phillip V of Spain brought fresh energy and new administrative methods to the decaying Spanish kingdom.

The merger of states reduces interstate transaction costs but increases intrastate transaction costs. The impetus to economize on transaction costs affects the number and size of nations. The appropriate forum (within a merged nation or across two sovereign nations) for resolving conflict depends on the political institutions available in each sphere and the nature of the potential conflict. The existence of the World Court, the willingness of nations to forego war as a means of settling disputes, and other methods of reducing interstate transaction costs reduce the optimal nation size. More generally, different national and transnational political institutions have different transaction costs and thus the comparative advantage of size depends on which political institutions are in place.⁵

² Communist systems often have inappropriate pricing mechanisms making international trade difficult. The resulting need for autarky creates a greater demand for a larger country.

³ Unfortunately, the rigid power-sharing structure and weak central government made Lebanon unable to cope with the arrival of the PLO, shifting demographics, and interference from its neighbors.

⁴ What were the advantages to W. Germany in joining with E. Germany? In the short run, there are great costs. But in the long run, the free movement of capital and labor will greatly increase the wealth of both countries.

⁵ I will not consider the endogeneity of political structure. I want to go beyond the standard public finance explanation for jurisdictions—that the extent of the jurisdiction covers the extent of the externality.

II. Historical Example

The ideas developed above can provide insight into historical events. My example of France and Poland in the nineteenth century is chosen for illustrative purposes only; it demonstrates the stance one takes in explaining history. A more thorough discussion would involve a separate article.

While not denying the role of the military in shaping the political map, my analysis places military power in a secondary position. First, military might and even military victory need not lead to territorial changes. For example, after Napoleon's defeat and his banishment to Elba, the Congress of Vienna extracted virtually no European territorial concessions from France although the allied armies had ended the war at the gates of Paris. Even after Napoleon's return and subsequent defeat at Waterloo, territorial concessions were minimal (the boundaries of France remained virtually unchanged from those at the start of the French Revolution); instead, more severe indemnities were to be paid by the vanquished nation. The end of the Franco-German War in 1871 found Paris surrounded, yet territorial concessions were limited to Alsace and Lorraine and control over the Papal territory. Instead of more territory, Germany received 200 million pounds sterling. A trade had been made. If they were rational, there was no other bargain (for example, France giving up more territory, but paying less indemnity) that would have made both sides better off.

Second, military might is often a result of other variables. These variables *may* be the underlying explanation for territorial change. The ability to raise large armies and finance a war depends on economic strength and a very effective political apparatus. Political skills needed to wage a war are positively correlated (but not perfectly) with those skills necessary for ruling a nation.

Napoleon is often viewed as a great military strategist, but he was also an effective administrator and statesman. Furthermore, his success was built on the many reforms of the French Revolution (including standardized taxes and centralized power).

Expansion of one country at the expense of another may be due to the more effective political structure and competent staffing of the expanding country (which may be reflected in their relative military capabilities). The same holds true for the reverse: a successful war of independence may result from the center being too politically weak to either rule the break-away state effectively or create a powerful military force.

A comparison of nineteenth century Poland and France is insightful. The flatness of Poland has always been used as a reason for its easy subjugation, but the partition and complete disappearance of Poland in the latter part of the nineteenth century was also due to its internal weaknesses. Polish nobility had been a very powerful force in maintaining the status quo; anyone could veto legislation and dissolve the assembly. The central government had neither substantial revenues, nor a well-equipped standing army, nor a bureaucracy to do the work of a state. Poland was in need of a more effective political apparatus. It got one by being gobbled up by its neighbors. A duchy remained under the control of Russia, but it did not maintain the name of Poland.

In contrast, France maintained most of her territorial integrity, despite having much of her territory occupied in three separate wars. An important difference between the two countries was that, with the exception of those times of internal strife, France had an effective national apparatus while Poland did not. To continue with the takeover metaphor, France is an example of green-mail while Poland is an example of a hostile takeover.

III. Summary

It is hard to condense the history and theory of the size of nations into a short paper. Even restricting the viewpoint to that

Since "externalities" can be dealt with across jurisdictions in a Coasian bargain, externalities alone cannot explain the size of the political entity.

of economic theory provides many disparate components. Therefore, I merely summarize some of the major stands of my argument.

I have argued that the role of military power in explaining the takeover (or breakup) of nations, while not insignificant, has been overemphasized—it is often an effect rather than a cause. At times, military strength may reflect underlying political power. A successful war of independence may occur because the center was too weak politically to either rule the break-away state effectively or create a powerful military apparatus. At other times, a more powerful military force may reflect the greater value to the country from occupying certain territory; that is, willingness to pay for military action partially depends on the gain from such activity. The biggest argument against the equality between military power and size of nations is that the conquering country has often given up captured territory for monetary and other indemnities.

When commitments are credible, then the size of nations tend toward the optimal (see my 1991 paper). Two nations would join together (separate) if the economies of scale and scope and the synergy produced by their union created greater (smaller) benefits than costs. Militarism still might be used by the strong to exploit the weak, but the tribute paid by the weak would not necessarily be territorial.

The merger of states reduces interstate transaction costs but increases intrastate

transaction costs. As international organization improves (the creation of the European Economic Community) and international transaction costs are reduced (most importantly, the threat of war is decreased and barriers to international trade are reduced), then the size of nations will be reduced. This is occurring in the Soviet Union and, to a lesser degree, even in Great Britain. As European integration increases, British integration is likely to decrease, with Scotland, for example, taking on a more independent role within Great Britain. Similar forces are at work in China. Power is shifting from the center to the provinces.

I have purposely omitted two of the standard arguments for nations—nationalism and ideology. Economists do not use such devices to explain firm conglomeration and divestiture and they should not use them to explain nation size either. The analysis need not be restricted to the political dimensions of nations. Many of the insights provided here can be applied to cities, religions, tribes, and clans.

The Technology of Conflict as an Economic Activity

By JACK HIRSHLEIFER*

People can satisfy their desires in two main ways: by *production* (for self-use, or for mutually beneficial trade with other parties), or else by *conflict* (i.e., by actual or threatened theft, robbery, confiscation, or litigation). Despite its evident importance, only recently has a systematic economics of struggle and conflict begun to emerge.¹

I. Technology and Conflict

Conflict, as opposed to mere failure of cooperation, comes about when one or more parties calls upon a special technology. To wit, a technology whereby some or all contenders for resources incur costs in an attempt to weaken or disable competitors. This definition is broad enough to encompass not only war but also strikes and lockouts, lawsuits, sibling rivalries within families, and redistributive politics. But, for concreteness here, I mainly use the metaphorical language of military combat.

The costs of conflict as an economic activity can include: 1) foregone opportunities, as when guns are produced rather than butter; 2) attrition of the resources actually devoted to combat, for example, military casualties; 3) collateral damage to productive resources. The prospect of collateral damage, intentional or unintentional, reduces the profitability of conflict. In fact, the retaliatory threat of collateral damage is, according to modern deterrence theory, the key to peace in a nuclear age. As a nonmilitary example, subsidy seeking is held somewhat in check to the extent that prospective beneficiaries recognize they will be incurring some share of the collateral

damage in the form of deadweight loss to the economy (Gary Becker, 1983). And scorched-earth tactics (imposing or threatening to impose collateral damage on oneself) may play a role not only in warfare but in corporate takeover struggles.

An operations research literature exists that looks into what might be called the industrial engineering of combat: for example, the vulnerability of submarines to depth bombs, the effectiveness of anti-aircraft guns placed on merchant ships, the tradeoff between training air crews versus actual mission time (Philip Morse and George Kimball, 1951). Of more interest to economists is the *macrotechnology* of conflict: how generalized resources devoted to struggle generate outputs in the form of gains and losses to each side.

Such an economic analysis of conflict may help explain not only the prevalence of war and peace, but also the sizes and shapes of nations, the distribution of power among social classes, the viability of two-party vs. multiparty political systems, strikes and lockouts in industry, sibling rivalry, why there are more lawsuits nowadays, and who wins in the battle of the sexes. On this vast range of topics I can offer here only some preliminary ideas, focusing upon how outcomes are constrained by the technology of conflict.

II. Conflict Models

Modeling of conflict can be said to begin with Frederick Lanchester (1916).² In his best-known formulation, letting F_1 and F_2 be force sizes at any moment, and α_1 and α_2 be fighting efficiency parameters, the attrition rates of the two forces can be repre-

*Department of Economics, University of California, Los Angeles, CA 90024.

²Robert Samz (1970) surveys a number of precursors of Lanchester.

sented by

$$(1) \quad dF_1/dt = -\alpha_2 F_2; \quad dF_2/dt = -\alpha_1 F_1.$$

Solving the differential equations indicates that the relative strengths vary with the squares of the force sizes. Whichever side is initially stronger inevitably grows stronger still, until the weaker is extinguished. This is probably too extreme, but even if it were valid, we would still have to consider both the costs and benefits of military victory.

In a simple version of such a model, each side $i = 1, 2$ seeks to maximize its steady-state income I_i . We can suppose that: (a) each side divides its endowed resources R_i between productive effort E_i and fighting effort F_i ; (b) aggregate income I is generated by the two sides' productive efforts; and (c) the respective shares p_i depend upon the fighting efforts. Thus:

$$(2a) \quad E_i + F_i = R_i$$

$$(2b) \quad I = \Omega(E_1, E_2)$$

$$(2c) \quad p_1 = \Gamma(F_1, F_2); \quad p_2 = 1 - p_1$$

$$(2d) \quad I_i = p_i I.$$

To actually solve this general equilibrium system, we would also have to specify a solution concept: Cournot, Stackelberg, or whatever.

The specification of the *productive technology* in (2b) involves some drastic simplifying assumptions, among them that: (i) all income I is jointly produced, and falls into a common pool available for capture; (ii) conflict activity does not damage the resources R_i or the productive process that generates income. In effect, the only costs of conflict recognized are the opportunity losses of devoting resources to fighting effort F_i rather than to productive effort E_i . The *conflict technology* Γ of equation (2c), which might be termed the Contest Success Function (CSF), is oversimplified, among other respects, by making no distinction between offense and defense. Or, looking at this in another way, the model does not

FIGURE 1. CONTEST SUCCESS FUNCTION AS THE MASS EFFECT PARAMETER k VARIES

provide any special advantage for status quo possession.

An attractive form for the CSF is the logistic function:

$$(3) \quad p_1/p_2 = \exp\{kF_1\}/\exp\{kF_2\}$$

$$\text{or} \quad p_1 = 1/[1 + \exp\{k(F_2 - F_1)\}].$$

Here k is a "mass effect parameter" scaling the decisiveness of fighting effort disparities. As plotted in Figure 1, the horizontal axis represents side No. 1's force F_1 , where by assumption the opposing force is fixed at $F_2 = 1$. (The efficiency parameters α_i are assumed equal to unity.) On the vertical axis is plotted p_1 , No. 1's fractional share of income (or, on an alternative interpretation, No. 1's *probability of winning*).

The logistic function squares with what might be called the first "stylized fact" of warfare: the tremendous advantage of being even just a little stronger than one's opponent. In more familiar economic terminology, we would expect to observe *increasing marginal returns* to force size F_1 so long as $F_1 < F_2$, with *decreasing marginal returns* holding thereafter—as is broadly consistent with military experience (T. N. Dupuy, 1987). Note also that p_1 remains positive even when zero fighting effort is invested, a feature consistent with a second stylized

fact: that there can be a peace either of subjugation (one side finds its optimal to choose zero fighting effort) or else of balanced settlement (both sides find it optimal to do so).³ Another implication of the logistic CSF is that *proportionately growing wealth* on the two sides works to the net advantage of the wealthier party. Thus, over time, smaller contenders may tend to be subjugated by larger ones, which perhaps helps explain a third stylized fact: the tendency toward fewer but larger states over historical time.

Underlying the logistic form is the premise that the numerical difference $F_1 - F_2$ between the fighting efforts determines conflict success. An alternative approach would be, as in the Lanchester model, to make success a function of the ratio F_1/F_2 . The ratio form turns out to be inconsistent, or only imperfectly consistent, with the stylized facts listed above. In particular, peace is impossible since a side unable or unwilling to fight loses everything. One interpretation is that the ratio form applies under "ideal" conditions such as an undifferentiated battlefield, full information, and unflagging effectiveness. But where what Clausewitz called "friction" plays a role (if there are sanctuaries and refuges, if information is imperfect, or where fatigue limits what a victor can do), the difference form better describes the outcome.

Foregoing possible generalization, for lack of space I turn instead to another question: the competition between the technology of conflict and the technology of peaceful production and exchange.

III. Technology of Conflict vs. Technology of Production and Exchange

For concreteness, suppose the production function Ω is such that

$$(4) \quad I = \Omega(E_1, E_2) = A(E_1^{1/s} + E_2^{1/s})^s.$$

Here A is a measure of the total productiv-

ity of the "factors" E_1 and E_2 , while s is an index of the complementarity between them. For given inputs, as s rises, income I will increase as well, and the marginal products $\partial I/\partial E_1$ and $\partial I/\partial E_2$ will also both rise.

In Figure 2a, given the E_2, F_2 choice of the other side, for contender No. 1 the mp_F curve shows the marginal product of fighting effort while mp_E represents the marginal product of productive effort. No. 1's best-response optimum is at the intersection. However, the curves will themselves shift in response to the opponent's choice of F_2 vs. E_2 , and they will also be sensitive to exogenous factors like changes in preferences, in wealth endowments, or in the Ω and Γ functions.

Suppose the complementarity index s between the parties' productive efforts were to rise. Then, as indicated in Figure 2a, No. 1's mp_E curve shifts upward. It might therefore seem that increased complementarity implies rationally devoting more effort to production and less to conflict. However, the increase in I puts more income at stake, so that fighting effort also tends to have a higher return. Thus the mp_F curve also shifts upward, so that the net effect remains unclear. This consideration exposes the fatal flaw in assertions that the growing interdependence among nations is making war obsolete.⁴ That same growing interdependence also typically raises the stakes of conflict—each side has more to gain from fighting and more to lose by failing to fight.

In Figure 2b, taking contender No. 2 as protagonist, we ask what happens when opponent No. 1 becomes richer than before. Normally, No. 2 can expect that an enriched No. 1 will be choosing higher levels both of productive effort and of fighting effort—larger E_1 and larger F_1 . Given positive complementarity, the larger E_1 will make the mp_E curve for No. 2 shift upward, so there

³See my 1988 article; see also Stergios Skaperdas (1990).

⁴Just before World War I, an immensely popular book by Norman Angell (1911) argued that the growing economic absurdity of modern war meant that the major powers of Europe would no longer find it advantageous to fight one another—or, at least, to persist in such a conflict for very long. Similar arguments are still heard today.

Marginal
productFIGURE 2a. EFFECT OF INCREASED
COMPLEMENTARITYMarginal
productFIGURE 2b. WHEN NO. 1 GET RICHER,
NO. 2 FIGHTS HARDER

is a force tending to induce No. 2 to revise his choice in the direction of productive effort E_2 . But there are two more powerful considerations working the other way: (i) aggregate income being higher, as before there is more of a prize to be fought over,

and (ii) the opponent's F_1 being larger means that No. 2 must invest more fighting effort just to retain what he already had. So a less well-endowed side will find it optimal to devote relatively more effort to fighting: "No. 2 tries harder."

IV. Some Implications of Conflict Technology

Individuals and groups can compete by employing the technology of conflict as an alternative to the technologies of production and exchange. To summarize only a tiny sample of the implications: *As regards peace or war*: Peace is more likely to the extent that the decisiveness of conflict is low or (though I did not have time to develop these points) if the stakes are small or if the technology favors the defense. More surprisingly, perhaps, increased productive complementarity between the parties does not systematically favor peace. *As regards relative success*: Evidently, a favorable force disparity $F_1 - F_2$ promotes success, thus conferring an advantage upon the better-endowed side. Also, greater decisiveness of conflict increases the benefit of such a disparity. However, the poorer side is generally motivated to invest relatively more heavily in fighting effort. So conflict can be an income-equalizing process. In fact, newly impoverished social groups do typically become more bellicose, newly enriched groups more pacific and accommodating.

GREENHOUSE WARMING[†]

International Trade in Carbon Emission Rights: A Decomposition Procedure

By ALAN S. MANNE AND RICHARD G. RICHELS*

In recent years, a number of proposals have been advanced for the limitation of carbon emissions. Some have argued that such limits would be costless, but our analysis suggests that there is no free lunch. (See our forthcoming paper.) We have attempted to estimate the costs but *not* the global benefits of slowing down climate change through carbon limitations. All computations were performed in parallel for five geopolitical regions. Except for oil trade, these regions were treated independently—as though there were no opportunity for international trade in carbon rights. For stimulating ideas on the politics and economics of negotiating an agreement on greenhouse gas emission permits, see M. Grubb (1989).

Whatever rule is adopted for the allocation of carbon emission rights, there are likely to be significant interregional differences in the value of these rights. International trade will be needed if economic efficiency is to be achieved. In the absence of such trade, there are likely to be significant distortions in the comparative advantage of individual locations for the production of

tradeable basic materials such as primary metals. These distortions could lead to counterproductive regulations and new forms of nontariff barriers to trade. This paper is intended to quantify the potential for international trade in carbon emission rights.

I. The Decomposition Procedure

Each individual region is viewed as a price taker, and as a possible importer or exporter. Each is coupled to the others through the international price of these rights. Since this is an intertemporal problem, the time path of prices must be determined so as to equilibrate supplies and demands during each period simultaneously. We can no longer formulate the overall problem as five independent nonlinear *optimizations*. Instead, we must solve an *equilibrium* problem in which all choices are integrated through an international market in carbon rights—even though each of the five agents has an independent objective function and resource endowments. For a masterful review of such computations, see H. Scarf (1984).

An equilibrium problem is easy to formulate, but this one suffers from the *curse of dimensionality*. Since each commodity is differentiated between regions and time periods, there are approximately 5000 prices and quantities to be determined. A problem of this size is about five times larger than can be handled by the best algorithms currently available. (See, for example, T. Rutherford, 1989.) As a practical alternative, we have turned to a decomposition procedure.

The decomposition principle was originally applied to linear programming by

FIGURE 1. DECOMPOSITION PROCEDURE

G. Dantzig and P. Wolfe (1961). These ideas were later adapted to a nonlinear equilibrium model of international trade by A. Mansur and J. Whalley (1982). This paper reports numerical results employing a procedure motivated partly by Dantzig-Wolfe and partly by Mansur-Whalley. There is price-guided decentralization, there are quantity responses from the individual regions, and there are quantity allocations of tradeable goods at the final iteration. Although the method works well here, there is no proof that it will converge under all circumstances. These issues are left as a challenge to subsequent investigators.

Figure 1 provides an outline of the procedure. 5R is an acronym that describes the parallel five region optimizations. These are performed in three modes: no trade in carbon rights, price-guided decentralization, and quantity-guided decentralization. In order to solve the master problem, we employ MINDIST (a minimum distance convex combination of the proposals received from the individual regions).

The only tradeables consist of carbon rights and a numeraire good produced in each region. Let π_{rt} denote the price of carbon rights in region r during period t . In equilibrium, this price will be identical in all regions. That is, $\pi_{rt} = \pi_t$ (for all t).

Let x_{rt} denote the net exports of carbon rights from region r during period t . Note that x_{rt} may be positive, negative, or zero.

In equilibrium, $\sum_r x_{rt} = 0$ (for all t). That is, the international market for carbon rights must clear during each period t . Our decomposition procedure is designed so that the *quantity* equilibrium conditions are met exactly. The *price* equilibrium conditions are met only approximately. If there are significant discrepancies in these prices, one cycles back to the second step of the algorithm and eventually arrives at a more efficient allocation of carbon rights.

II. An Illustrative Example

In this example, there is an international agreement that total carbon emissions be limited to their 1990 level of 5.7 billion tons during each year of the twenty-first century, but the shares in carbon rights change gradually over time. Initially (during the year 2000), carbon rights are distributed between regions in proportion to their 1990 level of emissions. At the end of the planning horizon (the year 2100), carbon rights are distributed in proportion to the 1990 level of population. This proposal is designed to avoid an abrupt change in the status quo, but over the long run it leads to an egalitarian distribution of carbon rights. The 1990 population base is chosen specifically so as to penalize those nations that fail to control their rate of population growth.

According to Figure 1, the first step in the decomposition procedure is to determine the carbon prices that would prevail within each individual region in the absence of trade. That is, we set $x_{rt} = 0$, and solve 5R for the prices π_{rt} . Figure 2 contains a typical set of numerical results for USA (United States), OECD (other OECD); SU-EE (Soviet Union and Eastern Europe); China and ROW (rest of world). Despite the differences from one region to another, there is a general pattern to these price trajectories. During the initial years, it is optimal to delay the use of carbon rights. Prices then rise at the same rate as the marginal productivity of capital in each region—about 5 percent annually. During the later years, carbon prices stabilize at \$250/ton. This level is determined by the cost difference between a carbon-free and a car-

FIGURE 2. CARBON PRICES—NO TRADE

bon-based backstop and by the carbon coefficient of the backstop. There is also an intermediate period during which the new technologies require time for market penetration, and the carbon tax therefore overshoots the backstop level.

Figure 2 provides an important insight. It takes no more than a back-of-envelope calculation to determine the carbon tax during the backstop phase. If all regions have identical energy supply options at that time, there is no motivation for trade. Each region can be self-sufficient in carbon rights. Alternatively, if there are systematic differences between regions, the carbon tax during the backstop phase will be determined by the least-cost region, and it will export carbon rights to the others. There is no need to construct an intertemporal equilibrium model in order to analyze international trade in carbon rights during the backstop phase.

An intertemporal model is useful only during the transition period—when prices are first rising and then falling toward the backstop level. Moreover, an intertemporal model is needed in order to indicate the beginning date for the backstop phase. A major simplification is suggested by Figure 2. It suggests that we can truncate the analysis of international trade in carbon rights in the year 2050. Virtually all five regions have reached the backstop phase by that point.

Now return to Figure 1. For each region r , the "no trade" price vectors $\pi_{r,t}$ are internally consistent. That is, these prices do not rise more rapidly than the marginal produc-

FIGURE 3. CARBON PRICES—WITH TRADE
(CYCLE 4)

tivity of capital. We may now use these price vectors in succession to solve 5R for the case of price-guided decentralization, allowing for positive or negative values of the net export variables $x_{r,t}$. Thus we first solve 5R using $\pi_{USA,t}$, the price vector that emerged from solving the USA submodel under the assumption of no trade. Similarly, we solve 5R using the price vectors $\pi_{OECD,t}, \dots, \pi_{ROW,t}$.

In general, we solve 5R for each of K carbon price vectors, and record the regional distribution of net exports as $x_{r,t}^k$ (for $k = 1 \dots K$). In the first cycle, there are only five carbon price vectors, and $K = 5$.

The principal inputs to the "master" problem are the net export records associated with each of the K price vectors. For a given price vector k , the *price-guided* version of 5R determines $\bar{x}_t^k = \sum_r x_{r,t}^k$ = the global level of net carbon exports during period t . In general, the k th price vector will *not* lead to a global equilibrium in net export quantities; that is, $\bar{x}_t^k \neq 0$. The master problem is formulated, however, so that a weighted average of these net export vectors will add up to zero. The criterion for the choice of weights is *minimum weighted distance* from zero net export demands. With the net export allocations $x_{r,t}$, we run the *quantity-guided* version of 5R (the bottom box in Figure 1). This leads to a new set of region-by-region carbon prices $\pi_{r,t}$. If these are sufficiently close to each other, we can terminate. Otherwise, we can use these prices to begin a second cycle of the price-guided version of 5R, etc. By the fourth cycle, we obtain the prices shown on

Figure 3. Note that the decomposition procedure leads to regional prices that match each other quite closely. That is, $\pi_{r,t} \approx \pi_t$. Using GAMS/MINOS, this procedure requires about four hours on a desk-top computer. See A. Brooke et al. (1988). Further details are available in an appendix that can be obtained upon request to the authors.

III. Additional Results

In this scenario, the United States and China would be the major importers of carbon rights. The Soviet Union and Eastern Europe would be an exporter during the initial years and an importer subsequently. The other two regions (OECD and ROW) would be the major exporters.

Trade could lead to a significant volume of international financial transfers. In 2020, the United States would import .3 billion tons of carbon emission rights. Valued at \$150/ton, this would amount to an expenditure of \$45 billion. It would not be easy for political leaders to justify transfers of this magnitude. On grounds of economic efficiency, however, this would be clearly preferable to a detailed regulatory system in which specific carbon conservation guidelines are mandated for each class of end user.

What are the economic costs of carbon restrictions, and what are the benefits from international trade? According to this example, we should not expect dramatic gains from trade. None of the five regions imports or exports more than 5 percent of the total global volume of carbon rights.

Because of year-to-year fluctuations, it is best to express the gains from trade in terms of their effect upon discounted macroeconomic consumption throughout the planning horizon. Consumption losses are defined to be the difference between consumption with and without limits upon carbon emissions. Employing a 5 percent real rate and discounting back to 1990, we obtain the results shown in Figure 4. With no trade, it would cost the United States about \$1700 billion during the twenty-first century to participate in the international carbon limitations program. With trade, the costs

FIGURE 4. CONSUMPTION LOSSES

would be lowered by about \$100 billion. Each of the other regions would also benefit modestly from trade.

Caveat. These numerical estimates should be viewed as illustrative, and are subject to change as we obtain a better understanding of the parameters underlying the model. At this point, our calculations do not allow for indirect effects upon international trade through changes in the production locations of carbon-intensive basic materials such as iron and steel. It is clear that different results will be obtained if we modify any of the input assumptions. This is precisely the purpose of a model. In the debate over the costs of reducing the rate of climate change, our aim is to promote "second-order" agreement—that is, to identify the specific factors that are crucial to an overall assessment of the costs and benefits of limiting carbon emissions.

Towards a Comprehensive Approach to Global Climate Change Mitigation

By RICHARD D. MORGENSTERN*

Almost a century ago the Swedish scientist Svante Arrhenius coined the term "greenhouse effect." Since then physical scientists have been debating the potential for and implications of a significant change in the earth's climate associated with an increase in anthropogenic emissions of carbon dioxide. Within the past decade, scientists have developed expanded (and presumably improved) models of the global atmosphere, along with a fuller understanding of trace gases other than carbon dioxide that may alter the global heat balance. A number of panels of distinguished scientists, while noting the many uncertainties, have, nonetheless, warned of the risk of serious and, for practical purposes, irreversible global warming associated with projected greenhouse gas (GHG) emissions.

Economists are quite new to the field and are just beginning to frame their issues. Yet even at this early stage, the two economic issues that seem most compelling are the "so what" question and the notion that "maybe the cure is worse than the disease." "So what" refers to the argument that, even if the physical and biological changes on earth are large, maybe the economic consequences of such changes are small. Economists recognize this argument as a call for an aggregate damage function (i.e., benefits of avoided damages). "Maybe the cure is worse than the disease" refers to the allegedly huge costs associated with any attempt to forestall or even significantly delay global warming. Economists recognize this

latter argument as a call for an aggregate mitigation cost function.

To date, William Nordhaus (1990) is the only economist intrepid enough to write about both damage and cost functions associated with climate change. His pioneering works presents a "resource steady-state" model that integrates a discussion of the potential impacts of climate change (i.e., benefits due to avoided damage) with a mitigation cost function for the purpose of determining the optimal level of control of GHGs. His principal conclusion is that beyond continuing the scheduled phase out of CFCs, only a modest reduction of CO₂ (as would be achieved by a carbon tax of perhaps \$5/ton or less) is warranted on an economic basis at this time.

Nordhaus outlines the truly global nature of the climate change issue, but because of data availability focuses his analysis on the United States. This practical approach ignores the very real possibilities that the damages of climate change may be greater and/or the marginal costs of emission reduction lower in developing countries. Both possibilities, of course, imply that the optimal control level of GHGs may be greater for the global economy than the United States alone. Although the present paper is (regrettably) subject to the same data constraints, this is potentially a very important limitation that should be emphasized at the outset. The bulk of this paper represents work in progress.

I. Climate Change Benefit/Cost Framework

The goal of policymaking is to design an efficient climate change mitigation strategy that maximizes (under uncertainty) overall welfare, including measured GDP and the value of nonmarket goods and services (i.e., "Green GNP"). Such a strategy should select an amount of net emissions reduction and/or adaptation at which the marginal

*Director, Office of Policy Analysis, U.S. Environmental Protection Agency, Washington, D.C. 20460. I acknowledge the helpful comments of Jim Broadus, Howard Gruenspecht, and Bruce Schillo. The views expressed herein are my own and do not necessarily represent the views of the EPA or the U.S. government.

benefit of reduced GHG concentrations equals the marginal cost of reducing GHG concentrations or engaging in adaptation. Actual emissions reductions would be achieved at minimum cost by choosing the set of least-cost mitigation options.

Benefits may arise from changing the timing or magnitude of such adverse effects of climate change as lower agricultural yields, impacts of sea-level rise, adverse effects on human health, degradation of recreation and leisure time, and lessened biological diversity. The costs of a mitigation strategy encompass the direct expenditures needed to reduce GHG emissions, to increase the uptake of GHG sinks, or to adapt. Direct mitigation expenditures include: limiting the use of CFCs, adopting lower emitting fuels, fostering reforestation, raising the height of bridges, and moving water and waste treatment facilities.

A full accounting of benefits and cost should not be limited to a simple summing of individual adverse impacts or direct mitigation expenditures. Rather, a thorough analysis should reflect a general equilibrium framework with full social accounting. Moreover, the ancillary benefits or effects of any emissions mitigation strategy must also be incorporated in the benefit/cost calculation. These include the health and/or welfare benefits (due to a reduction in criteria air pollutants) or the energy security benefits of an energy saving measure and, conversely, the potentially lower agricultural yields as a result of the reduced CO₂ fertilization.

II. Benefits Estimates

Nordhaus derives many of his calculations of the economic impacts of climate change from a recent EPA report (1989) that developed estimates of the physical consequences associated with an assumed doubling of CO₂-equivalent concentrations of GHGs in the atmosphere. He concludes that, "[f]or the bulk of economic activity, non-climate variables like labor skills, access to markets, or technology swamp climatic considerations in determining economic efficiency" (1990, p. 17). By his estimation, the economic sectors likely to be

most severely affected by climate change are farming and fisheries. Nearly 90 percent of the economy is characterized as being negligibly affected by climate change. Nordhaus estimates that damage due to a 3°C warming in the middle of the next century is likely to equal one-quarter percent (0.25 percent) of annual U.S. national income. He allows that "inadequately studied or inherently unquantifiable" effects may raise the total to 1 percent of income, with an upper bound "unlikely to be larger than 2 percent of total output" (p. 20).

A review of Nordhaus' estimates suggests that the damages of global climate change may be larger in dollar amount in the categories he has monetized. Further, the damages may be broader in their scope, potentially affecting numerous other categories that he has neither provided dollar estimates for nor considered in a qualitative manner. Specifically, economic impacts due to sea-level rise have been revised to include an empirical study of the value of lost land, to add the value of land to the cost of constructing protection for sheltered areas, and to correct a computational error in the EPA report used in the cost calculation of protecting open coasts (see J. G. Titus et al., 1991). The combined effect of these revisions is an approximate doubling of Nordhaus' estimate of the annual economic effects of sea-level rise to \$10.6 billion (which also has the effect of doubling GNP losses from 0.25 to 0.5 percent). Both agricultural impacts and the effects of climate change on electricity operating and capital cost could also be substantially higher than Nordhaus allows (using high-end estimates from the EPA report could raise impacts in Nordhaus' categories to as much as 1.5 percent GNP).

Beyond reestimating the damage in categories that Nordhaus allows may be severely affected, a larger concern is for omitted or poorly defined categories. Some are relatively easy to measure and inherently monetizable, others are difficult to quantify and can best be weighed using some mix of quantitative and qualitative analysis. Still other categories such as preservation of coastal wetlands, old growth forests and biological diversity, with their attendant option

and existence values, are difficult if not impossible to quantify. All of which argues for more research on benefits and a plea to avoid the simple conclusion that if we cannot measure the benefits with precision, they effectively have zero or low value to society.

III. Comprehensive Approach

While much attention has focused on CO₂ limits in the context of climate change mitigation strategies, it is but one (albeit an important one) of a number of GHGs. Others include methane (CH₄), chlorofluorocarbons (CFCs), nitrous oxides (N₂O), and ozone (O₃). Of additional concern are gases that are not themselves GHGs, but are chemically active in the atmosphere and influence the concentration of GHGs. Examples of these are volatile organic compounds (VOCs), carbon monoxide (CO), and nitrogen oxides (NO_x). In addition, HCFCs which are important interim CFC substitutes should be included in a thorough analysis.

A comprehensive approach to GHG mitigation policy, at a minimum, should 1) encompass all direct and indirect GHGs, and 2) account for differences in the relative contribution of each gas to global warming. As to the second point, the Intergovernmental Panel on Climate Change (IPCC) (1990) has recently published "Global Warming Potential" (GWP) values for numerous GHGs. The GWP values allow emissions of GHGs to be expressed in a common metric ("carbon equivalents") that incorporates the differences in radiative forcing effect among GHGs and integrates that effect over the gases' atmospheric lifetimes, accounting for varying decay profiles and interactive (indirect) effects.

The IPCC GWP values relate trace gas emissions to a single physical effect—radiative forcing. A more elaborate index could be expanded to reflect the comparative effect of trace gas emissions on all physical phenomena and then translate those into socioeconomic impacts. Such an index has been suggested as a "Global Change Index." (See John Reilly, 1990; Richard Stewart and Jonathan Wiener, 1990.) One must ac-

knowledge, however, that a comprehensive approach to climate change mitigation (using the GWPs or a more elaborate index) faces numerous practical problems, including difficulties in inventorying gases and accounting for the locational, temporal, and source-specific nature of many of the direct and indirect GHG effects.

IV. Emissions and Cost Estimates

Table 1 presents estimates of total U.S. GHG emissions given current governmental policies for the years 1987, 2000, and 2010. The difference between the low and high estimates is due strictly to different CO₂ projections: the high CO₂ estimate is derived from the official U.S. submission to the IPCC, and the low CO₂ estimate is derived from the recent work of Dale Jorgenson and Peter Wilcoxon (1990). Subject to a long list of caveats discussed in the referenced papers, (weighted) U.S. emissions of all GHGs are projected to be approximately the same in the year 2000 as in 1987 (see Alexander Cristofaro, forthcoming; Cristofaro and Joel Scheraga, 1991). For the year 2010, estimates range from a slight increase (4 percent) to virtually no change. The base case scenarios indicate that an increase in CO₂ emissions (14–24 percent) will be offset by decreases in other gases covered by the Montreal Protocol (primarily CFCs) and the Clean Air Act.

Given these base case emissions scenarios, the question for policymakers is: What can be learned about the costs of meeting various GHG goals?

If the mitigation goal is to cap the overall weighted level of GHGs during the next 20 years (including so-called Montreal Protocol gases), only a limited amount of additional government intervention may be needed because current government energy and environmental policies are sufficient to keep total GHG emissions (expressed as carbon equivalents) below 1987 levels in the year 2000. In 2010, total emissions are projected to be only 4 percent above current levels in the high scenario, and essentially the same as 1987 levels in the low scenario.

If, instead, the goal is to stabilize or reduce CO₂ emissions or to reduce non-Montreal Protocol GHGs, additional control programs would be necessary. The rate of increase of CO₂ in the low scenario, however, is less than the rate of projected U.S. population growth (currently 0.7 percent per year). The rate of increase of CO₂ in the high scenario is only slightly more than projected population growth. Thus, existing government programs may be sufficient or nearly sufficient to limit per capita CO₂ emissions to today's levels in the years 2000 and 2010. More ambitious goals would require larger reductions.

A number of additional control opportunities exist that have not been systematically analyzed in the context of current policy. Methane is 21 times more potent than CO₂ in its radiative forcing contribution over a 100-year period and, thus, methane control may be an important component of GHG policy. Control opportunities include improved management, recovery, and fuel use of methane from animal waste, coal mines, solid waste landfills, and the anaerobic decomposition of sewage sludge. NO_x is 40 times more potent than CO₂. Although the 1990 Clean Air Act will result in over 2 million tons of NO_x reductions, other technically feasible NO_x control opportunities exist. CO is 8 times more potent than CO₂. Tighter tailpipe standards and oxygenated fuel requirements mandated by the 1990 Clean Air Act could be broadened or other-

wise strengthened. For all methane, NO_x, and CO options, additional analysis of total program cost and benefits, including complete fuel cycle analysis and health and welfare benefits, should be conducted before controls are implemented.

A number of studies have looked at the costs of controlling CO₂. The estimates of control costs vary widely, largely due to different assumptions regarding emission baseline levels, reduction targets, GDP and population growth rates, rates of technological change, estimates of capital mobility and malleability, ease of factor substitution, relative energy prices and, importantly, underlying model structure. Technology-driven end-use models generally project significant potential for cost-effective energy savings (i.e., net savings). A U.S. Department of Energy (1990) white paper projects the potential for cost-effective efficiency gains (reductions in demand) of 14 percent below otherwise projected consumption levels in 2010. Other "bottom-up" studies project larger cost-effective or "technological potential" savings. Bottom-up approaches lead to interesting behavioral, policy, and analytic questions: How much of the cost-effective potential can be captured? How best to capture it?

The CO₂ control cost estimates exist from a variety of macroeconomic studies. Generally, these studies, which include short- and long-run models and differ widely in their methodologies and input assumptions, estimate positive control costs. Typical results estimate that a 10 to 20 percent reduction from base levels will require a carbon tax of between \$10 and \$75 per ton, and GNP will be 0.2 to 4.0 percent lower than otherwise. Among the studies surveyed by Nordhaus is the study by Jorgenson and Wilcoxon (J/W). The J/W study is based on a 35-sector econometric model of the U.S. economy estimated through 1985 with endogenous technical change. Economic growth is an output rather than input of this model, and is projected to grow at a 2 percent annual rate over the 1990–2000 period, with a slight decrease thereafter. Preliminary results from J/W of a carbon tax analysis indicate that emissions can be maintained at 1990

levels through the imposition of a phased carbon tax that rises to a level of approximately \$17 per ton in 2020. (Assumptions would have to be altered to develop credible projections beyond 2020. The \$17 per ton estimate, in part, reflects an assumed high degree of capital malleability in the utility sector; the model is being revised to address this aspect, and adjustments will likely result in cost estimates somewhat higher.)

A carbon tax, absent accommodative measures, and depending upon its timing and scope, could have inflationary and/or recessionary impacts. The use of a "tax shift" mechanism could help minimize the net social cost of CO₂ control; revenues generated through a carbon tax could be rebated or offset by reductions in income and/or business taxes. Importantly, selection of the precise measure used to recycle the carbon tax can have a significant differential effect. To illustrate this phenomenon, consider a recent study by Data Resources, Inc. (DRI/McGraw Hill, 1991) that analyzed the differential macroeconomic impacts of a gasoline tax sufficient to maintain light duty vehicle carbon emissions at 1989 levels through 2010. In one scenario analyzed, the gasoline tax revenues were accompanied by a reduction in personal income taxes, resulting in a GNP loss of 0.4 percent in the year 2000. In another scenario, the gasoline tax revenues were accompanied by a reduction in payroll taxes (paid by businesses), resulting in a GNP virtually unchanged from baseline levels.

The above two scenarios highlight the possibility of addressing an environmental externality through a Pigouvian tax while minimizing the adverse macroeconomic effects (caused by the resulting change in fiscal policy) through the adoption of other appropriate policies. A GHG mitigation policy that shifts the tax base toward the incorporation of an environmental externality and away from other business taxes (in some sense, trading a good tax for a bad) is likely to minimize the impact on total national income, although tax burdens and economic impacts on different sectors of the economy will vary.

V. Conclusion

Apart from the scientific uncertainties, a complex set of issues surround the economic analysis of climate change. The calculation of net benefits related to optimal policy strategies hinges on at least four key factors: 1) the breadth of quantifiable damages considered; 2) the number of GHGs for which practical control options are devised (and ancillary net benefits included); 3) the consideration of base case growth, technological damage, capital malleability, and related factors; and 4) the extent to which other policies (i.e., tax recycling/shifting) can be used to offset the macroeconomic effects of GHG policies. A great deal more research is needed—especially an attempt to look at both costs and benefits in an international context. I encourage other economists to engage the issue.

A Sketch of the Economics of the Greenhouse Effect

By WILLIAM D. NORDHAUS*

Over the last decade, scientists have studied extensively the greenhouse effect, which holds that the accumulation of carbon dioxide (CO₂) and other greenhouse gases (GHGs) is expected to produce global warming and other significant climatic changes over the next century (see Stephen Schneider, 1989). The present study presents an economic approach for analyzing policies to slow climate change.

I. Scientific Background

In weighing climate change policies, the prospects for global warming and the linkage between human activities and the emissions of GHGs form a key building block. The major GHGs are carbon dioxide, methane, nitrous oxides, and chlorofluorocarbons (CFCs). In this analysis, I translate each GHG into its "CO₂ equivalent" in total warming potential. Current emissions are about 8 billion tons of CO₂ equivalent per year (carbon weight). CO₂ is the dominant GHG, currently contributing about 80 percent of the total potential global warming of the major GHGs.

On the basis of climate models and climate history, scientists expect that a doubling of CO₂ (or its radiative equivalent) will in equilibrium lead to an increase in the global mean surface temperature of 1 to 5 degrees Centigrade (C), an increase in precipitation and evaporation, a small rise in sea level, and a number of other more uncertain effects.

A complication in studying the climatic impact of rising GHGs involves the time delay of several decades, arising because of

the thermal inertia of the oceans, in the reaction of climate to increasing atmospheric concentrations. In the model used here, I simplify by assuming that the temperature-adjustment process takes the following form:

$$(1) \quad \dot{T}(t) = \alpha\{\mu M(t) - T(t)\}$$

$$(2) \quad \dot{M}(t) = \beta E(t) - \delta M(t)$$

where dots over variable represent time derivatives and t = time; $T(t)$ = increase in global mean surface temperature since mid-nineteenth century from accumulation of GHGs (°C); $M(t)$ = anthropogenic atmospheric concentration of CO₂ equivalent GHGs (billions of tons of CO₂ equivalent); $E(t)$ = anthropogenic emissions of CO₂-equivalent GHGs (same units as M); μ = .005 = linearized equilibrium increase in global mean temperature in response to increasing CO₂ equivalent concentration (°C per billions tons carbon); α = .02 = delay parameter of temperature in response to radiative increase (per year); β = .50 = airborne fraction of CO₂ equivalent emissions; and δ = .005 = annual rate of removal of CO₂ equivalent from the atmosphere (per year).

Equation (1) is a simple first-order equation often used to represent climate dynamics, while equation (2) is a simplified two-box diffusion model of the carbon cycle. These equations are calibrated or estimated from current models or historical data.

II. Economic Aspects of Greenhouse Warming

Greenhouse warming is the granddaddy of all public goods, involving climate change over the indefinite future. Because of the climate externality, the production of greenhouse gases will differ from the efficient level. We can analyze the costs and benefits of the greenhouse effect and policies in terms of two fundamental functions: the

*Yale University and the Cowles Foundation, New Haven, CT 06520. This paper is an abridged version of my longer study (1990b), and I am grateful for insightful comments from many people, with particular thanks to Alan Manne, Tom Schelling, James Sweeney, and Paul Waggoner. This research was supported in part by the National Science Foundation.

greenhouse damage function that describes the costs to society of the changing climate, and the *abatement cost function* that describes the costs that the economy pays to slow greenhouse warming. I analyze here efficient strategies, those that maximize overall net economic welfare ("Green National Product").

Economic theory tells us that, in a competitive economy with no other externalities and where controls are efficiently designed, certain properties hold. To begin with, the first units of GHG reduction are virtually free because of the zero market price on the GHG emissions. Second, we know that the cost function increases in the level of abatement.

Next examine the greenhouse damage function that measures the cost to the economy of higher levels of GHGs (measured relative to some baseline). In contrast to the cost function, we know little about the shape of the damage function. We suspect that greenhouse warming will hurt the global economy, but because of the fertilization effect of CO₂ or the attractiveness of warm climates, the greenhouse effect might on balance actually be economically advantageous. In addition, the costs of climate changes are likely to be sensitive to the speed of climate change.

I next present a stylized model of the relationship between economic growth and climate change which incorporates the dynamics of climate change and of investing to slow climate change. I study the impact of greenhouse policies upon an idealized global economy in the middle of the next century. The key assumption is that the economy is in "resource steady state," which signifies that all *physical* flows in the global economy are constant although the real *value* of economic activity may be increasing. I allow for "balanced resource-augmenting technological change" at rate h .

In the steady state, per capita consumption is given by

$$(3) \quad c(t) = y^* e^{ht} \{ g[E^*] - \phi[T^*] \}$$

In this equation, the asterisks indicate steady-state values. The new variables are $c(t)$ = per capita consumption at time t ; y^*

is a constant; $y(t) = y^* e^{ht}$ = per capita output before any emissions reduction and with no climate damage; $g(E)$ = cost of emissions reduction; and $\phi(T)$ = damage function from greenhouse warming.

It is assumed that it is desirable to maximize a social welfare function that is the discounted sum of the utilities of per capita consumption. This is in essence a standard optimal growth model extended to include climatic variables. In the model used here, the critical parameter is $r - h$, the difference between the discount rate on goods (r) and the growth rate of the economy. This will be relevant because, while we discount future damages at r , in our resource steady state the damages will be growing at the rate of economic growth (h).

To calculate the optimal level of emissions reduction in our simple model, let us perform a variational experiment of increasing emissions by ΔE in period 0. A fair amount of algebra will show that the optimal level of emissions is given by

$$(4) \quad g'(E^*) = \mu \beta \phi'(T^*) \Gamma$$

where Γ = a present-value factor = $\alpha / [(r + \delta - h)(r + \alpha - h)]$. Equation (4) states that the optimal degree of reduction of GHGs comes where the marginal current cost of reducing GHG emissions equals the present value of the marginal damage from higher concentrations. The present-value factor Γ can be interpreted as the number of years, in present value, of equilibrium-CO₂-doubling climate damage that occur when a one-shot concentration increase, equal to the initial CO₂ concentration, takes place at time zero. In the section that follows, I estimate the parameters of this equation and then derive the optimal rate of emissions reduction for GHGs. (A preliminary analysis of a non-steady-state trajectory incorporating several regions and growth of emissions is contained in my 1990a paper.)

III. Empirical Estimate of the Optimal Strategy

I have elsewhere estimated the economic parameters underlying the optimal condition in equation (4). These estimates are

FIGURE 1

highly uncertain, and the reservations are given in the background documents.

There are numerous estimates, particularly for CO_2 , of the cost of reducing GHGs (see the survey in my forthcoming article). Figure 1 shows the overall marginal cost curve and the cost curves for different GHGs derived in that study. With current annual emissions of 8 billion tons of CO_2 equivalent, these data suggest that a modest reduction of GHG emissions can be obtained at low cost. After a 10 percent reduction, however, the curve rises as more costly measures are required. A 50 percent reduction in GHG emissions is estimated to cost almost \$200 billion per year in today's global economy, or around 1 percent of world output. This estimate is understated to the extent that policies are inefficient or are implemented in a crash program.

Studies of the impacts of climate change are sparse. They cover few countries and have major methodological shortcomings, so our estimates of the impact of greenhouse warming are only suggestive. Studies indicate that of the major industries, agriculture is the one most likely to be severely affected by climate change, although the sign of the impact is uncertain. Sea-level rise will be costly to coastal regions, but the impact is likely to be very gradual. Other affected sectors are construction, energy, recreation, and water systems, but the impacts here are

likely to be imperceptible compared to the background noise for many decades.

For the numerical estimates used here, I examined the impact of climate change coming from an equilibrium doubling of CO_2 equivalent atmospheric concentrations. This is assumed to produce a 3°C rise in global mean surface temperature along with the associated changes in climate. In an uncontrolled economy, this is likely to arrive in the second half of the next century. In the aggregate and in terms of those variables we have been able to quantify, I estimate that the net economic damage from a 3°C warming is likely to be around $\frac{1}{4}$ percent of national income for the 1981 sectoral distribution of the United States (we call this the "low" estimate). This figure is clearly incomplete, for it neglects a number of areas that are either inadequately studied (nonmarket sectors) or difficult to quantify (value of species loss or aesthetic values). We might raise the number to around 1 percent of total global income to allow for these unmeasured and unquantifiable factors, although such an adjustment is purely *ad hoc* (this is the "medium" estimate). It is not possible to give precise error bounds around this figure, but my judgement is that the overall impact upon human activity is unlikely to be larger than 2 percent of total output (this is the "high" estimate).

IV. An Efficient Policy for Slowing Greenhouse Warming

We can now provide estimates of an efficient policy for slowing greenhouse warming, where this is described in equation (4). In this analysis, it is assumed that the baseline policy is one in which there are no greenhouse policies in place.

Let us begin tabulating in Table 1 the calculated costs and damages that are drawn from the findings above. Column (1) shows the percentage reduction in GHGs from an uncontrolled level. Columns (2) and (3) shows the costs of GHG reductions from Figure 1. The final column displays the estimated total discounted damages associated with the given level of reduction of GHG emissions, this figure being based on the middle impact estimate.

TABLE 1—CALCULATION OF COSTS AND BENEFITS FOR DIFFERENT LEVELS OF REDUCTION OF GREENHOUSE GAS EMISSIONS

Source: For both costs and benefits, calculations use 1989 levels of world greenhouse gas emissions, prices, and world output. Cost estimates shown in Figure 1. Background data are presented in my 1990b paper.

Note: Col. 1 = Reduction of GHG emissions (as percent of base level); Col. 2 = Marginal cost of reduction (\$ per ton CO₂); Col. 3 = Total cost of reduction (bill. of \$/yr); Col. 4 = Total benefit of reduction (bill. of \$/yr).

^aMost efficient level of control of GHG emissions for medium damage level.

The efficient level of GHG reduction is shown in Table 1 for the middle level of damages and for a discount rate that is 1 percent above the growth rate (i.e., $r - h = .01$ per year). This estimate corresponds to the middle damage estimate of \$7.30 per ton of CO₂ equivalent. Equating the marginal damage with the marginal cost leads to an efficient level of control of 11 percent of GHG emissions. At the efficient control level, the total global annual cost of reducing emissions is around \$3 billion while the total global annualized benefits are estimated to be around \$6 billion.

The same outcome is illustrated in Figure 1, which puts together the empirical marginal costs and damage curves. The horizontal axis shows the percentage reduction in GHGs. The curve marked "MC: All GHGs" is my estimate of the marginal cost of GHG reduction. The horizontal curves marked Medium and High Damage correspond to marginal damage estimates of \$7.30

and \$66 per ton of CO₂ equivalent; these correspond to annual damages of 1 and 2 percent of total output, respectively. The first figure uses the middle discount rate of $(r - h)$ equal to 1 percent, while the second uses a value of $r - h$ of 0.

The efficient policy is found at the intersection of the relevant damage curve with the marginal cost curve. The medium case leads to a reduction of 11 percent of GHG emissions. At the low damage estimate, not shown, there is very little GHG emission reduction for its own sake. At the extreme, high damage estimate, about one-third of total GHG emissions would be efficiently reduced.

Figure 1 also allows us to determine the contribution of different GHGs to the total reduction. For the medium damage estimate, virtually none comes from trees, 2 percent from the reduction of CO₂ and 9 percent comes from the reduction in CFC emissions. All options suggest a significant reduction in the use of CFCs and that little can be realized through forestry options. The main difference among the policies is the extent to which CO₂ emissions are reduced.

V. Conclusions

This study examines an economic approach to policies concerning greenhouse warming. It uses an approach in which the optimal degree of control of GHGs is set at that point where the marginal costs of control are equal to the discounted marginal damages from climate change. For the low damage function (that includes only identified costs and uses a middle discount rate), I estimate the marginal damage of greenhouse gases to be about \$1.80 per ton of C in CO₂ equivalent, which implies very little CO₂ abatement. For the medium damage function, that assumes damage from greenhouse warming of 1 percent of GNP, the cost is reckoned at \$7.30 per ton carbon; in this case, the efficient reduction is 11 percent of total GHG emissions. In the high damage case, with damages taken to be 2 percent of total output and with no discounting, GHG emissions are reduced by about one-third.

Second, the appropriate level of control depends critically upon three central parameters of the climate-economic system: the cost of control of GHGs, the damage to the human societies from greenhouse warming, and the time dynamics as reflected in the rate of discount of future goods and services along with the time lags in the reaction of the climate to emissions. The efficient degree of control of GHGs would be essentially zero in the case of high costs, low damages, and high discounting; by contrast, in the case of no discounting and high damages, the efficient degree of control is close to one-third of GHG emissions.

Finally, it should be emphasized that this analysis has a number important oversimplifications. It greatly simplifies many of the intricate economic and climatic complexities by taking a global view of economic activity and a simple dynamic specification of emissions, concentrations, and economic growth. Moreover, this study bases the economic damage assumptions upon the 1981 sectoral composition of the U.S. economy and assumes that this composition will hold for the global economy in the mid-twenty-first century. In addition, it ignores other routes for investing society's resources (such as factories, education, research, and health) and focuses on a single tradeoff between future and present consumption. Furthermore, the calculations omit other potential market

failures, such as ozone depletion or air pollution, that might reinforce or weaken the logic behind greenhouse-gas reduction. And finally, it ignores the issues of uncertainty, in which risk aversion and the possibility of learning may modify the stringency and timing of control strategies. Notwithstanding these simplifications, the approach laid out here may help clarify the questions and identify the scientific, economic, and policy issues that must underpin any rational decision.

GENDER AND PRODUCTIVITY

The Role of Off-the-Job vs. On-the-Job Training for the Mobility of Women Workers

By LISA M. LYNCH*

The transition from school to work is typically a period in which many young workers experience a wide range of different jobs and experience some of their most rapid wage growth over their working life. Robert Hall (1982) has estimated that the first 10 years of an individual's working career will include approximately two-thirds of all lifetime job changes. Robert Topel and Michael Ward (1988) found that over half of young male new entrants held six or more jobs over the first 10 years of their work experience. Only one young male worker in twenty held a single job for 10 years in their sample. All of this suggests that young workers' early years in the labor market involve several employment transitions.

The purpose of this paper is to examine for young workers in their first years of work the determinants of leaving an employer. In particular, this paper focuses on the role of different types of training on the probability of leaving an employer. In previous work (1990) I have examined the impact of private-sector training on the determination of wages and wage growth of young workers and reached the following conclusions. First, formal company-provided on-the-job training (ON-JT) appears to be highly firm-specific in the United States and, therefore, is not portable from employer to employer. Company-provided training raises

wages in the current job but has no effect on the wages earned in subsequent employment. Second, formal off-the-job training (OFF-JT) received from "for-profit" proprietary institutions has little effect on the wages earned on the current job, but it does raise the expected wage in subsequent employment. Finally, there are important differences by race, gender, and education level in the probability of receiving different types of formal training and in the impact this training has on wages and wage growth.

These findings have several implications for the impact of training on mobility. One implication is that if company-provided training is primarily firm-specific, then the probability of leaving an employer should decline if a young worker has experienced some ON-JT. An additional implication is that if a worker participates in an OFF-JT program, it appears that the worker should be more likely to leave the current employer. In this case, OFF-JT allows a young worker to change career paths and find a "better match." Using data from the *National Longitudinal Survey Youth (NLSY)* cohort, this paper examines in detail the factors that influence the probability of new entrants leaving their first job, including the differential effects of company-provided training, apprenticeships, and training from for-profit proprietary institutions.

I. The Theoretical Framework

There are a variety of explanations of why young workers change their employment status so often in the early years of their careers and then seem to settle down into more stable employment. In the unionized sector, where seniority rules determine lay-

*MIT Sloan School of Management, Cambridge, MA 02139, and NBER. Thorough research assistance was provided by Pamela Loprest and funding for this research was provided by the Department of Labor, grant number E-9-J-9-0049. The views expressed here do not necessarily represent the official position of the Department of Labor.

off policies, young workers are more at risk of being laid off in a downturn. Even in the nonunionized sector, many firms use seniority as a major determinant of whom to lay off in a period of falling demand.

There are other explanations of the higher turnover rates of young workers, however, that have little to do with the state of demand. The three main theoretical explanations include job search, job matching, and on-the-job training. Job search theory, as detailed by Steven Lippman and John McCall (1976), states that information about where to find a job and the nature of that job are difficult to acquire, especially for younger workers. Workers will accept employment and remain in that job as long as the wage paid in that job exceeds the alternative wage. Therefore, workers who earn more relative to their alternative wage are less likely to quit.

An alternative explanation of turnover behavior can be found in Boyan Jovanovic (1979a,b; 1984). In the Jovanovic learning model, both workers and firms "learn" about the unobserved characteristics of each other over time. As tenure increases, the quality of the job match is revealed as firms observe workers' actual productivity and workers discover the nonpecuniary aspects of their job. In this model there are two countervailing forces for the relationship between tenure and the probability of leaving an employer. On the one hand, "better" workers remain with employers longer, leading to negative duration dependence in the probability of leaving a job. On the other hand, as "bad" matches are revealed, the turnover probability will rise over time.

The process of ON-JT within the human capital model as described by Jacob Mincer (1974) implies that as workers acquire firm-specific training, their productivity and, consequently, wages will rise. Therefore, the probability of leaving an employer will fall with training and tenure since the wage will rise relative to the alternative wage. In addition, employers will be less likely to lay off those workers in whom they have invested in specific skills. However, if most of the initial training for young workers is general, there will be either no effect on the quit

probability or the quit probability may even rise.

All of these theories are not mutually exclusive and clearly some combination of all of these factors influences the probability of a young worker remaining with an employer. Consequently, it is not the purpose of this paper to distinguish between different theories. Rather, it would be more useful if precise data on employment spells and training could be found, to try to establish the links between different types of training and turnover behavior.

There have been relatively few empirical studies that have attempted to examine the role of training, demand, and other factors in predicting the probability of leaving an employer. This is primarily due to the lack of accurate data on the timing of private sector training and the lack of detailed employment histories for workers. Recent exceptions include R. Mark Gritz (1988) and Mincer (1988). Gritz uses data from the early years of the *NLSY* and finds that private-sector training (not distinguishing between different sources of training) increases the amount of time in total employment for females, but decreases the amount of time males were employed. Unfortunately, most of the training data he uses are taken from the period before the employment history begins. Mincer uses data on training and mobility from the *Panel Study of Income Dynamics*. The training variable comes from the answer to the following question in the 1976 and 1978 interviews: "On a job like yours how long does it take the average new person to become fully trained and qualified?" While this is potentially a very broad measure of training, it does not measure how much training has actually occurred for the specific respondent. In addition, it captures training information for the current job, not previous employment.

Using data from the *NLSY*, it is possible to examine in more detail than has been possible in the past, the role of training, the general state of demand, and other personal characteristics in determining turnover. The probability of leaving employment (for whatever reason) is also known as the haz-

ard rate or failure rate in renewal theory. The hazard rate or turnover probability can be expressed as

$$(1) \quad h(t) = g(t) dt / (1 - G(t)),$$

where $g(t)dt$ is the probability of leaving an employer between time t and $t + dt$, $1 - G(t)$ is the probability of being employed at time t , and t is the duration of the current spell of employment. In this paper, the following Cox proportional hazards model is used:

$$(2) \quad h(t; z) = h_0(t) e^{zB},$$

where $h_0(t)$ is an arbitrary and unspecified baseline hazard function and z is a vector of characteristics including training. The Cox model is convenient for dealing with right censoring and it is nonparametric in the sense that it involves an unspecified baseline hazard instead of making further distributional assumptions such as those required for the Weibull or log-logistic hazard. However, this means that it will not be possible to measure whether or not there is negative or positive duration dependence in employment, but this is not a key focus of this paper.

In a model of the role of training in the probability of leaving an employer, it is important to be able to allow training to occur over time with the employer. Allowing for covariates such as training to be time dependent implies

$$(3) \quad h(t; z(t)) = h_0(t) e^{z(t)B},$$

where $z(t)$ is a vector of all fixed and time varying covariates.

As discussed in D. R. Cox and D. Oakes (1984), the components of the vector $z(t)$ can be divided into the following three categories of variables: treatments that vary with time; intrinsic properties of individuals/jobs that are time invariant; and exogenous time-varying variables.

Obviously the different types of private-sector training are the treatment variables of interest. Examples of time-invariant per-

sonal and job characteristics include gender, race, education, occupation, industry, union status, location of the job in an urban area, and whether or not the respondent is disabled. Time-varying exogenous variables include the local unemployment rate, marital status, and the number of children.

II. The Data

The *NLSY* is a survey of 12,686 males and females who were 14 to 21 years of age at the end of 1978. These respondents have been interviewed every year since 1979 on all aspects of their labor market experience. It is possible to construct a detailed weekly employment history for all the respondents since January 1, 1978. This can be matched with a similar event history of schooling and training from the private sector. The data on types of training received (other than governmental training or schooling) are some of the most comprehensive data available on private-sector training. Respondents were asked about what types of training they had received over the survey year (up to 3 spells) and the dates of training periods by source. Potential sources of training include business college, nurses programs, apprenticeships, vocational and technical institutes, barber or beauty schools, correspondence courses, and company-provided training.

The training data are divided into the variables: company training (*ON-JT*); apprenticeships (*APT*); and training obtained from for-profit proprietary institutions outside the firm (*OFF-JT*). The variable *OFF-JT* includes training obtained from business courses, barber or beauty school, nurses programs, vocational and technical institutes, and correspondence courses. All of these types of training programs are independent from training received in a formal regular schooling program that is included in the schooling variables. However, the questions ask about only those spells of training that lasted at least 4 weeks (they did not have to be full time). This suggests that the *NLSY* measure of training is more likely to capture formal training spells than informal on-the-job training.

For this analysis, a subsample of the 12,686 respondents has been selected. I have excluded the 1280 respondents in the military subsample from the analysis. I have also deleted any respondent who had completed school before the 1979 interview year. The final sample is a pooled sample of young workers who have left school and not returned to school for at least 4 years (permanently out of school). Therefore, this sample is made up of 5 waves of school leavers: those who left in 1979, 1980, 1981, 1982, and 1983. In addition, the respondents had to have obtained a job in the first year after permanently exiting school. The estimated hazard models the determinants of the turnover probability for the first job after leaving school permanently for this sample.

Almost three-quarters of the sample leave their first employer during the first 4 years after school. The average duration of employment (including those still employed after 4 years) is about a year and a half. Almost 17 percent of the sample experienced some form of formal training in their first job, but the distribution of this job training by source varied substantially by demographic group. College graduates were much more likely to have received some form of ON-JT while those with just a high school diploma were more likely to have participated in some form of OFF-JT. Women were more likely than men to have received some form of OFF-JT, but there was little difference in the probability of receiving ON-JT by gender (not controlling for other factors).

III. The Results

The results obtained from estimating the Cox proportional hazard with time-varying covariates are presented in Table 1. The time-invariant intrinsic characteristics of the individuals/jobs in Table 1, equation 1, that seemed to influence the probability of leaving an employer included being disabled, union status, race, and school level. Disabled respondents were more likely to leave their employer as were blacks and those with a high school degree or less. Being

^aDenotes time-varying covariates.

male or Hispanic had no differential effect on the expected duration of employment in the first job. Being employed in a job covered by a collective agreement or being a college graduate significantly lowered the probability of leaving the first employer. Of the time-varying exogenous covariates, the local unemployment rate was significant, implying that those who were in high unemployment areas were less likely to leave their employer. The hurdle for these youths

in high unemployment areas was most likely getting the job in the first place. In addition, those workers who were married were more likely to remain with their first employer. With regards to the training variables, those young people who had some formal *ON-JT* were much less likely to leave their employer while those who participated in some form of *OFF-JT* were more likely to leave. This seems to suggest that *ON-JT* is more firm-specific, while *OFF-JT* is more general. These findings are consistent with the results on training and wages reported in my earlier paper.

In equation 2 of Table 1, an additional variable is added that is the difference between the log of the current wage (that varies with time) and a log predicted wage. The predicted wage is obtained by using the estimated coefficients from a log wage equation for the starting wage for this sample. Those individuals who are being paid less than their predicted alternative wage are more likely to leave their employer as shown in equation 2. None of the previous findings are altered except that the degree of significance of *OFF-JT* improves.

In equations 3 and 4 the proportional hazard is reestimated for males and females. Now the results changed dramatically depending upon whether the worker is male or female. For example, it is striking to find that for men being disabled or just a high school graduate has no effect on the turnover probability. In addition, both *ON-JT* and *OFF-JT* are now insignificant. On the other hand, *ON-JT* increases the length of time in employment in the first job for women and *OFF-JT* increases their turnover probability. Having more children increases the probability that women will leave their employer, while marital status has no effect on the transition probability.

IV. Conclusions

While this paper has attempted to shed new light on the skill formation process of young workers and the consequences of this on their patterns of mobility, there are still many issues that remain unresolved. This paper has modeled the determinants of the

duration of the first job after school, not subsequent employment. As the *NLSY* age, future research should examine, for example, how some of the gender, race, and educational differences change over time. It would also be interesting to examine the hazard rates by broad industry and occupational categories. Finally, it would be important to see how robust the findings are after additional work is done to address the endogeneity issue for training.

Nevertheless, there is a story that emerges from the results in this paper for young workers and private-sector training. Company training in the United States is firm-specific, even for young workers in their first job. Young workers entering the labor market can receive both good and bad draws from the labor market. There are some workers who get a bad draw who appear to move to better employment by investing in off-the-job training. Those in good jobs are more likely to obtain on-the-job training that results in higher wages and a lower probability of leaving the firm. These effects are particularly strong for women.

The Impact of Nonmarket Work on Market Wages

By JONI HERSCH*

It is frequently asserted that balancing a job and family responsibilities is more difficult for women than men. Support for this notion stems from evidence that women, in essence, work two jobs—one in the market and one at home. While the popular press has focused on the stress and frustration associated with the so-called “second shift,” work at home may also affect the labor market situation of women. The types and locations of jobs acceptable to women who assume heavy household responsibilities may be limited. In addition, nonmarket work may have a direct effect on earnings by reducing the amount of energy and effort available for market work.

Economists have largely overlooked the direct effects of household responsibilities on earnings, instead focusing attention on the effect of differences in household roles on human capital accumulation. According to human capital theory, women who bear the majority of household and child care responsibilities may expect discontinuous labor force participation and fewer total years in the labor force than men. Thus women will have fewer years over which to reap the rewards, and hence will optimally choose to acquire less human capital. Further, employers will provide less specific training to women workers in anticipation of their higher turnover.

By this argument, the lower average earnings of women are attributable to lower average quantities of human capital. Yet women are invariably found to earn less than men with equivalent human capital characteristics. Further, as the labor force participation rates of men and women continue to converge, differences in human capital will decrease in importance as an explanation of wage differences between men and women. Yet most women, even those with market jobs, continue to assume the

primary responsibility for household chores. The purpose of this paper is to examine the direct effect on market productivity of the dual responsibilities of market and nonmarket work.

I. Data Set and Empirical Results

To investigate the direct role of housework in affecting wages, I use data from the 1987 *Panel Study of Income Dynamics (PSID)* (Wave 20). This data set has information on 7061 households. Each head of household was asked to respond to a series of questions about sources and amounts of income, labor market activity, and personal background, and to answer a parallel set of questions about their spouse, if the head is married.

For the purposes of this study, the advantage of this data set is that it contains a measure of time spent on housework. Heads of households were asked to answer the following question, for themselves and for their spouse: “about how much time do you (does your spouse) spend on housework in an average week? I mean time spent cooking, cleaning, and doing other work around the house.”

The average values of time spent on housework for the sample members that are employed or temporarily laid off are reported in Table 1. The values are reported by gender, marital status, and presence of children under age 18 in the housing unit. As one would expect, the average values of time spent on housework for parents of either gender exceed the corresponding values for individuals without children under age 18.¹
